Platelet-activating factor (PAF), a potent biolipid mediator, is involved in a variety of cellular transduction pathways and plays a prominent role in inducing inflammation in different organs. We used K5.hTGF-β1 transgenic mice, which exhibit an inflammatory skin disorder and molecular and cytokine abnormalities with strong similarities to human psoriasis, to study the pathogenic role of PAF. We found that injecting PAF into the skin of transgenic mice led to inflammation and accelerated manifestation of the psoriatic phenotype by a local effect. In contrast, injecting mice with PAF receptor antagonist PCA-4248 lowered the PAF level (most likely by depressing an autocrine loop) and neutrophil, CD68+ cell (monocyte/macrophage), and CD3+ T-cell accumulation in the skin and blocked progression of the psoriasis-like phenotype. This effect of PAF blockade was specific and similar to that of psoralen–UV-A and was paralleled by a decrease in abnormally elevated mRNA and/or protein levels of T-helper type 17 cell–related cytokines IL-17A, IL-17F, IL-23, IL-12A, and IL-6 and its transcription factor signal transducer and activator of transcription 3. In contrast, PCA-4248 treatment up-regulated mRNA levels of cyclooxygenase-2 and IL-10 in dorsal skin and release of IL-10 in serum and skin. Interfering with PAF may offer the opportunity to develop novel therapeutic strategies for inflammatory psoriasis and associated comorbidities, including metabolic syndrome and atherosclerosis, in which the IL-17 axis may be involved. (Am J Pathol 2011, 178:699–708; DOI: 10.1016/j.ajpath.2010.10.008)
served with clinical improvement after treatment.\(^8\) Moreover, elevated levels of arachidonic acid and eicosanoids and elevated expression of human nonpancreatic phospholipase A\(_2\) were measured in psoriatic tissue.\(^9\) Phospholipase A\(_2\) is one of the key enzymes for PAF formation because it enzymatically cleaves arachidonic acid from the sn-2 position of cell membrane phosphatidylcholine, and an acetyl residue is subsequently transferred to the free hydroxyl from CoASAc to form biologically active PAF.\(^3\) Besides, PAF was identified and isolated in scales from psoriatic patients.\(^2,11\) Last but not least, Travers et al\(^{12,13}\) suggested that PAF and its receptor play a direct role in keratinocyte pathogenesis.

We recently used K5.hTGF-\(\beta\) transgenic mice,\(^{14,15}\) which exhibit a skin phenotype and molecular and cytokine abnormalities with strong similarities to human psoriasis, to study the therapeutic mechanisms of psoralen–UV-A (PUVA) phototherapy and observed that impaired function of regulatory T cells and increased cytokine levels of the IL-23/T-helper type 17 cell (Th17) pathway were responsible for the psoriatic phenotype in this mouse model.\(^{16}\) Treatment of K5.hTGF-\(\beta\) transgenic mice with PUVA not only cleared the psoriatic skin manifestations but also suppressed the Th1 milieu and the IL-23/Th17 pathway and induced the Th2 pathway and IL-10–producing CD4\(^+\)CD25\(^+\)Foxp3\(^+\) regulatory T cells with disease-suppressive activity in K5.hTGF-\(\beta\) transgenic mice. The PAF pathway may affect T-cell responses and favor development of the inflammatory Th17 pathway,\(^{17}\) in which T cells produce the proinflammatory cytokines IL-17A (IL-17) and IL-17F and, to a lesser extent, TNF and IL-6.\(^{18}\) Indeed, expression of IL-17 seems to be increased in human autoimmune diseases, including multiple sclerosis,\(^{19,20}\) rheumatoid arthritis,\(^{21,22}\) lupus erythematosus,\(^{23}\) and psoriasis\(^{23}\) as well as in animal models of autoimmunity.\(^{24}\) We, therefore, were interested in testing the hypothesis that PAF/PAF receptor interaction plays a role in induction of the psoriatic phenotype and Th17 cytokine abnormalities in K5.hTGF-\(\beta\) transgenic mice.

**Materials and Methods**

**Animals**

K5.hTGF-\(\beta\) transgenic mice (on Hsd:ICR/CD-1R background) expressing wild-type (WT) transforming growth factor (TGF)-\(\beta\) in the epidermis were used, as previously described.\(^{16}\) All the animals were maintained with alternating 12-hour light and dark cycles in temperature-and humidity-controlled facilities approved by the Austrian government. Water and food were provided ad libitum. All the animal procedures were approved by the Austrian government, Federal Ministry for Science and Research, through protocol no. BMFWK-66.010/0034-BrGT/2006 and 66.010/79-C/GT/2007. Mice were 12 to 16 weeks old at the start of the experiment and were age and sex matched in each experiment.

**PAF or Serotonin Injection**

Dorsal skin of the mice was injected intracutaneously with 100 ng of PAF (\(\beta\)-Acetyl-y-O-alkyl-L-\(\alpha\)-phosphatidylcholine from bovine heart lecithin; Sigma-Aldrich, St. Louis, MO) or 5 \(\mu\)g of serotonin (Sigma-Aldrich) or bovine serum albumin vehicle control in a final volume of 50 \(\mu\)L. After 24 and 72 hours, biopsy specimens were collected for H&E staining.

**PAF or Serotonin Receptor Blockade**

The PAF receptor antagonist PCA-4248 and the serotonin receptor antagonist ketanserin tartrate were purchased from Biomol Research Labs Inc. (Plymouth Meeting, PA). Stock solutions were prepared by dissolving PCA-4248 or ketanserin tartrate in dimethyl sulfoxide and diluted further in PBS before injection into mice. Mice were injected with PCA-4248 or ketanserin tartrate i.p. (10 mg/kg) twice weekly for 4 weeks.

**PUVA Treatment**

The backs of the mice were shaved using an electric clipper 1 day before PUVA treatment. The remaining hair was then removed by the application of a commercial depilation cream for 3 to 5 minutes (Depilan sensitive) and subsequent cleaning with water. Mice were painted on their backs with 200 \(\mu\)L of 8-methoxypsoralen (Sigma-Aldrich) in 95% ethanol (at a concentration of 0.1 mg/ml) or were left untreated. The mice were then kept for 15 minutes in individual compartments of standard cages to allow penetration of 8-methoxypsoralen. Irradiation with UV-A was performed using a Waldmann UV236A irradiation system equipped with two fluorescent PL 36W/09-PUVA light tubes (emission range, 315 to 400 nm; peak, 365 nm; Waldmann Medizintechnik, Villingen-Schwenningen, Germany) at a mean irradiance of 8.55 mW/cm\(^2\), as previously described.\(^{16}\) The PUVA was administered to the dorsal skin of the mice on a subphototoxic level at a dose of 0.25 J/cm\(^2\) or near-photo- toxic level of 0.50 J/cm\(^2\) UV-A twice weekly (Monday and Thursday or Tuesday and Friday) for 4 weeks.

**Skin Disease Severity Score**

A specific mouse skin disease severity score composed of a rating from 0 to 3 for the symptoms of erythema, infiltration, and scaling based on the macroscopic appearance of the skin was used weekly to monitor the skin status of individual mice in a blinded manner, as previously described.\(^{16}\) Briefly, each symptom was scored separately as 0 (not present), 1 (mild), 2 (moderate), or 3 (severe). The scores were summed up, taking into consideration the area involved, resulting in a maximal score of 9.

**Tissue Collection**

Mice were sacrificed 48 hours after the final treatment, and blood, skin, and ear samples were collected. Serum was frozen and stored at \(-70^\circ\)C for enzyme-linked immunosorbent assay (ELISA). Approximately 1 cm\(^2\) of central dorsal skin per mouse was excised, fixed immediately in 4% buff-
were subjected to homogenization for mass spectrometry or was submerged in RNA later solution (Applied Biosystems, Foster City, CA) and stored at −70°C for later mRNA analysis.

**Immunohistochemical Analysis**

Stainings were performed on paraffin-embedded sections of mouse dorsal skin with monoclonal rat antimonouse CD68 (clone, FA-11; Abcam, Cambridge, England) (1:50) or polyclonal rabbit antimonouse CD3 (Abcam) (1:100). Briefly, primary antibody was applied after pretreatment of the sections with EDTA at pH 8. Dako biotinylated polyclonal rabbit antirat IgG or Dako Multi-Link antirabbit, antimonouse, and antirabbit IgGs Multilink system (Dako, Glostrup, Denmark) was used for visualization of the staining, according to the manufacturer’s instructions.

**Immunofluorescence Staining**

Direct or indirect stainings were performed on paraffin-embedded sections of mouse dorsal skin with either phycoerythrin-conjugated antimonouse rat IL-10 (clone, JES5-16E3; BD Pharmingen, San Diego, CA) (1:50) or antimonouse rabbit signal transducer and activator of transcription 3 (STAT3) (Abcam) (1:100). Goat antirabbit IgG fluoroscein isothiocyanate (Abcam) (1:50). Goat antirabbit IgG fluorescein isothiocyanate (Abcam) (1:100) was used as secondary antibody for STAT3. Briefly, antibody was applied after pretreatment of the sections with EDTA at pH 8 followed by blocking with 5% bovine serum albumin/0.5 Tween 20. After incubation at room temperature for 1 hour, slides were incubated with secondary antibody and coverslips were mounted onto the slides using VECTASHIELD mounting medium with DAPI (Vector Laboratories, Burlingame, CA). Images were acquired by using a DP71 digital camera (Olympus, Center Valley, PA) attached to an Olympus BX51 microscope.

**Assessment of Microscopic Skin Inflammation**

Epidermal hyperplasia was quantified in dorsal or ear skin of H&E-stained sections by counting epidermal cell layers and measuring the thickness of the epidermis from the basal layer to the stratum corneum using the calibrated eyepiece micrometer of a microscope. Semiquantitative scoring of the inflammatory infiltrate in the upper or lower dermis was performed in the dorsal skin of H&E-stained sections by counting epidermal cell layers (at final magnification, ×100). The number of neutrophils in H&E sections and CD68+ cells (monocytes/macrophages) and CD3+ T cells in the dermis of immunohistochemically stained sections from dorsal skin was assessed in at least 10 to 15 randomly selected areas per section (at final magnification, ×200). All measurements were performed in a blinded manner. Results were first averaged per mouse and then were averaged per treatment group for statistical analysis. Images were acquired by using a DP71 digital camera attached to an Olympus BX51 microscope.

**PAF Analysis Using Mass Spectrometry**

Mouse skin was homogenized in 2 ml of PBS/methanol (1/1 v/v). Each sample was spiked with 25 ng of 1-O-Octadecyl-2-butanoyl-sn-glycero-3-phosphocholin (Avanti Polar Lipids Inc., Alabaster, AL) as internal standard immediately. Subsequently, lipids were extracted according to the method of Bligh and Dyer. Lipid extracts were taken to dryness and were resuspended in 200 μL of chloroform/methanol (2/1 v/v). A HyPURITY Advance C18 (polar embedded), 100 × 2.1-mm, 3-μm column (Thermo Fisher Scientific, Waltham, MA) was used. The gradient ran from 0% to 95% B in 1 minute, then to 100% B in another 12 minutes, where it was held for 8 minutes. The flow rate was 250 μL/min (4000 QTRAP; Applied Biosystems, coupled to an 1100 HPLC; Agilent, Palo Alto, CA). Data acquisition was performed using multiple reaction monitoring scanning. The spray voltage was set to 5000 V, curtain gas to 10 psi, source temperature to 400°C, declustering potential to 90 V, and collision energy to 35 V for all analytes. The nebulizer gas was at 60 psi, and the turbo gas was at 50 psi. Peak areas were calculated using Analyst software (Applied Biosystems) for PAF, identified by mass, fragmentation, and retention time. The amount of PAF was calculated using the standard curve method.

**Cytokine ELISA**

The Th1/Th2/Th17 cytokines Multi-Analyte ELISArray Kit (SABiosciences, Frederick, MD) was used to analyze a panel of 12 cytokines involved in Th cell biology using a conventional ELISA protocol according to the manufacturer’s instructions. The cytokines represented by this array are IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-13, IL-17A, IL-23, interferon-γ, TNF-α, and TGF-β1.

**Quantitative RT-PCR**

RNA was isolated from mouse dorsal skin using the QIAGEN Fibrous Mini Kit (QIAGEN Inc., Valencia, CA). RNA was reverse transcribed using the First Strand cDNA Synthesis Kit (Roche Diagnostics GmbH, Mannheim, Germany), and quantitative RT-PCR was performed using pretested primers to STAT3, IL-17A, IL-17F, IL-12A, IL-6, COX-2, and IL-10 (SuperArray Biosciences Corp., Frederick, MD). The reactions were run on an Applied Biosystems 7900HT system by using RT² SYBR Green/ROX qPCR Master Mix (SuperArray Biosciences Corp.). The ΔΔCt method was used to normalize transcript to glyceraldehyde-3-phosphate dehydrogenase and to calculate fold change compared with the WT control.

**Statistical Analysis**

Data are expressed as mean ± SEM. Statistical differences among experimental groups were determined by using unpaired or paired two-tailed t-tests as appropriate. Statistical significance was set at P < 0.05.
Results

PAF Receptor Blockade Prevents Whereas PAF Accelerates Progression of Skin Disease in K5.1.hTGF-β1 Transgenic Mice

To study the role of PAF and its receptor in the pathogenesis of psoriasis-like skin disease in the K5.1.hTGF-β1 transgenic mouse model, we used the PAF antagonist PCA-4248. This antagonist has been previously shown to inhibit not only UV-induced immunologic alterations\(^{3,26,27}\) but also nonmelanoma skin cancer induction and progression and UV-induced skin damage in hairless mice\(^{28}\), as well as experimental human melanoma lung metastasis in nude mice.\(^4\) We injected WT or K5.1.hTGF-β1 transgenic mice with either the PAF antagonist PCA-4248...
We therefore looked for the effect of the serotonin receptor antagonist ketanserin tartrate on the pso-

or PBS as vehicle control twice weekly for 4 weeks. We found that treatment with PCA-4248 blocked the psori-

otic disease progression in K5.hTGF-β1 transgenic mice compared with with vehicle-injected control litter-

mates (Figure 1, A and B). The stop of progression of skin disease in transgenic mice was paralleled by the reduced histologic alterations observed in PCA-4248–treated K5.hTGF-β1 transgenic mice compared with vehicle-injected control littersmates (Figure 1, C and D). Whereas vehicle-treated K5.hTGF-β1 transgenic mice exhibited a hyperplastic epidermis of approximately four cell layers and a thickness of >60 μm and a dermis with a superficial mixed inflammatory infiltrate consisting of mononuclear cells and neutrophils, CD68++ cells, and CD3+ T cells, such skin alterations were significantly diminished in the skin of PCA-4248–injected transgenic mice after 4 weeks of treatment (Figure 2B). The PCA-4248 injection particularly reduced the mean ± SEM number of neutrophils (from 27.8 ± 3.2 to 17.9 ± 1.4), and CD3++ T cells (from 42.4 ± 1.1 to 26.7 ± 2.6) in the dermis of transgenic mice (Figure 2B). In contrast, we found that injecting PAF into the skin of transgenic mice led to inflammation and accelerated the manifestation of the psoriatic phenotype by a local effect, as observed on the macroscopic level (data not shown) and confirmed on the microscopic level by density of skin infiltration and epidermal hyperplasia. The effects of PAF in accelerating the disease phenotype were more prominent after 72 hours compared with 24 hours after single intracutaneous injec-

tion (Table 1). In addition to being a PAF receptor antagonist, PCA-4248 may also act as a serotonin receptor antagon-

ist.29,30 We, therefore, looked for the effect of the serotonin receptor antagonist ketanserin tartrate on the psori-

otic phenotype in K5.hTGF-β1 transgenic mice. However, we found that blocking serotonin receptor with ketanserin tartrate did not affect macroscopic skin phenotype (see Supplemental Figure S1A at http://ajp.amjpathol.org) or microscopic skin alterations in the transgenic mice (data not shown). Furthermore, intracutaneous injection of serotonin did not accelerate the psoriatic disease phenotype of the transgenic mice (see Supplemental Figure S1B at http://ajp.amjpathol.org). These findings indicated that the effect of PCA-4248 in blocking PAF was specific and that serotonin did not play a (major) role in psoriatic skin disease abnormality of K5.hTGF-β1 transgenic mice.

Mice were injected intracutaneously with PAF (100 ng) or with vehicle control. Biopsy samples were collected at injection sites at different time points after injection (24 and 72 hours) for histologic evaluation, as defined in Materials and Methods.

*Data are given as mean ± SEM.

†P < 0.05.

‡P < 0.01 (unpaired t-test) comparing the respective PAF versus vehicle treatment values (n = 4 to 8 per treatment and time point).
the skin of the mice by means of mass spectrometry. We found that vehicle-injected K5.hTGF-β1 transgenic mice had significantly increased mean ± SEM PAF levels (0.81 ± 0.16 ng/100 mg) in the skin compared with WT littermates (0.10 ± 0.10 ng/100 mg) at the end of the 4-week treatment protocol (Figure 4A; see Supplemental Figure S2 at http://ajp.amjpathol.org). The PAF receptor blockade with the antagonist PCA-4248 (but not vehicle control) reduced the mean ± SEM PAF levels in the skin of K5.hTGF-β1 transgenic mice to 0.11 ± 0.02 ng/100 mg, a level similar to that observed in WT control mice (Figure 4). We previously demonstrated that PUVA given at subphototoxic (0.25 J/cm²) or near-phototoxic (0.50 J/cm²) doses were effective in clearing psoriasis-like skin symptoms in K5.hTGF-β1 transgenic mice. We, therefore, were interested in determining the effect of PUVA on PAF levels in the skin of K5.hTGF-β1 transgenic mice. We found that blockade of the PAF receptor with the antagonist PCA-4248 reduced the mean ± SEM PAF levels in the skin of K5.hTGF-β1 transgenic mice to 0.17 ± 0.06 and 0.29 ± 0.10 at 0.25 J/cm² and 0.50 J/cm², respectively (Figure 4A). The trend that the PAF-depressing effect of the lower PUVA dosage of 0.25 J/cm² was greater than that of the higher dose of 0.5 J/cm² is consistent with the potential role of PAF in the pathogenesis of the skin disease in K5.hTGF-β1 transgenic mice, in which the lower, subphototoxic PUVA dose was also slightly more effective in reducing the psoriasis-like skin symptoms in the mice. This is also in line with the clinical knowledge that under certain circumstances, PUVA doses that are too high can trigger or aggravate psoriasis by the so-called Koebner phenomenon. Moreover, we previously provided evidence that exposure of normal mouse skin may lead to the production of PAF and/or PAF-like molecules with immunosuppressive properties, depending on the PUVA dosage used.

Discussion

The PAF receptor blockade not only stopped disease progression at the macroscopic and microscopic levels (Figures 1 and 2) but also reduced the PAF level in the skin (Figure 4). Although the exact mechanism by which PAF receptor blockade reduces PAF levels remains to be determined; the most likely explanation is simple interruption of the known PAF autocrine loop and/or interference with leukocyte (eg, polymorphonuclear leukocyte) infiltration into the skin; the PAF receptor antagonist is inhibiting PAF formation, especially because these cells produce large amounts of this mediator.

We also found that blockade of the PAF receptor with the antagonist PCA-4248 depressed the abnormally elevated protein levels of IL-6, IL-12, IL-17A, and IL-23 and increased IL-10 levels in serum (Figure 3A) and significantly reduced mRNA expression of STAT3, IL-17A, IL-17F, IL-12A, and IL-6 in the dorsal skin of transgenic mice (Figure 3D). This is important because recent studies described the significance of the Th17 pathway and its involvement in model systems of autoimmunity, including...
psoriasis. The development and maintenance of psoriatic lesions have been linked to the secretion of cytokines and chemokines, including Th17-related cytokines, such as IL-17A, IL-17F, IL-23, IL-12, and IL-6. For instance, Teunissen et al. showed detectable levels of IL-17 mRNA in lesional psoriatic skin but not in nonlesional skin and that CD4^+ and CD8^+ clones derived from lesional psoriatic skin could produce IL-17 after stimulation with CD3/CD28 antibodies. The importance of the IL-17 pathway in K5.hTGF-β1 mice is also supported by the observation that blocking by injection with anti–IL-17 monoclonal antibody also stops the progression of the psoriatic skin disease in the model. At first sight, this seems to contradict the study by Fitch et al suggesting that the inflammatory skin disease in their K5.hTGF-β1 mice did not depend on the IL-23/Th17 pathway. However, the animals they used exhibited eosinophilic skin infiltration and highly elevated lesional IL-4 levels and high serum IgE levels, in contrast to the characteristics of the K5.hTGF-β1 mice originally described by Li et al. The latter findings were confirmed in our study, in which the mice had normal expression of Th2 cytokines, including IL-4 (Figure 3A).

We also found that blockade of the PAF receptor with PCA-4248 significantly reduced neutrophil infiltration in the dermis of transgenic mice (Figure 2). This effect may have been mediated via negative regulation of leukotactic factors, such as the functional murine IL-8 homologues CXCL1/KC and CXCL2/MIP-2. This is of clinical relevance because the abundance of PAF, eg, induced by intradermal injection into human skin, induces local swelling, wheal and flare responses, intravascular congestion, and neutrophil accumulation with the development of a cellular infiltrate primarily composed of lymphocytes and histiocytes. This is in line with our finding that PAF injection into the skin accelerated the psoriatic phenotype of the transgenic mice (Table 1). It is also important to mention that there is evidence of cross talk between human neutrophils and Th17 cells by the way that IL-17A and IL-17F, two of several cytokines produced by Th17 cells, can indirectly induce the recruitment of neutrophils. Consequently, PCA-4248 treatment may also have diminished the accumulation of CD68^+ cells and CD3^+ T cells in the dermis of transgenic mice (Figure 2).

In addition, we noted that blockade of the PAF receptor activated the transcription of COX-2 and the transcription and expression of IL-10 in the skin (Figure 3, C and D) and its release in the serum (Figure 3A). The transcription of COX-2 after PAF receptor blockade may reflect the involvement of this enzyme in an antipsoriatic gene transcription process that includes IL-10 establishment in K5.hTGF-β1 transgenic mice. This finding is in line with reports by other researchers, who concluded that COX-2–mediated prostaglandin E_2 up-regulates IL-10, which down-regulates IL-12 production.

The observation that IL-10 induced by PAF blockade may be responsible for inhibiting progression of the psoriatic phenotype in K5.hTGF-β1 transgenic mice is intriguing because recombinant IL-10 has been shown to be clinically effective in the treatment of psoriasis in hu-
mians and is one of the main mediators of the effects of PUVA, another highly effective treatment modality of psoriasis. Importantly, the functional relevance and significance of PAF receptor blockade and the subsequent reduction of PAF in the K5.hTGF-β1 transgenic mouse model are supported by findings from a previous study in which treatment during a 4-week period with the same doses of PUVA as used in this study led to improvement of the psoriatic phenotype of transgenic mice, accompanied by normalization of abnormally elevated cytokine levels in the skin and serum, including the Th1 and Th17 pathway and induction of IL-10. Similar to PUVA treatment of K5.hTGF-β1 transgenic mice, we also observed on PCA-4248 injection a decreased skin level of STAT3, a transcription factor that directly binds to the IL-17A and IL-17F promoters, analogous to other Th cell subsets, initiates Th17 commitment and links activated keratinocytes and immunocytes required for development of psoriasis in another transgenic mouse model. Furthermore, STAT3 has been shown to be an important regulator for other inflammatory cytokines, such as IL-6 and IL-12, both down-regulated by PAF blockade in this study (Figure 3). In this context, it has also been previously shown that STAT1 and STAT3 translocate to the nucleus after PAF stimulation, and there was attenuation of STAT3 phosphorylation by PAF receptor antagonists.

Taken together, the results of this study demonstrate that binding of PAF to its receptor is essential for psoriatic disease progression in the K5.hTGF-β1 transgenic mice and that PAF down-regulation and subsequent modulation of transcription factors such as STAT3 and downstream cytokine networks by a PAF receptor antagonist such as PCA-4248 or PUVA treatment has disease-suppressive activity. This implies that PAF blockade may be an option for the clinical development of antipsoriatic treatment. This particularly concerns less the chronic plaque type but more the inflammatory variants of the disease, such as localized pustular psoriasis (ie, palmoplantar psoriasis of Barber-Königsbeek or acrodermatitis continua of Hallopeau) and generalized pustular psoriasis (von Zumbusch type), which are characterized by massive neutrophilic accumulation with formation of microabscesses in the skin. The complications of the latter condition can be fatal, usually as a result of the protean manifestations of severe systemic disease, congestive heart failure, and intercurrent infections. There is an urgent need for new treatments for the latter conditions because antipsoriatic drugs, such as the biologicals (including anti-TNF-α and anti–IL-12/23 antibody), have been used only in single cases but have not yet been studied in controlled clinical trials and are not approved in these psoriasis variants. In addition, the blockade of PAF may be advantageous compared with other antipsoriatic strategies because it may confer additional anticarcinogenic efficacy, being of particular value for patients with psoriasis prone to skin cancer due to previous treatment. Moreover, interference with PAF and the downstream IL-17 pathway may also be attractive to prevent complications of comorbidities in psoriasis, especially metabolic syndrome and cardiovascular disease.

Indeed, the IL-23/IL-17 axis is stimulated in obesity and can accelerate atherosclerosis. The blockade of PAF may not only offer the opportunity to down-regulate IL-17 and consequently diminish psoriatic skin manifestations, as shown herein, but may also prevent platelet aggregation and vasculopathy of psoriatic comorbidity.

Acknowledgments

We thank the staff of the Center for Medical Research (Medical University of Graz) for its continuous support. Ms. Ulrike Schmidbauer for providing expertise and support in performing immunohistochemical staining, and Dr. Xiao-Jing Wang (University of Colorado, Denver), for providing the original K5.hTGF-β1 transgenic mouse strain.
