Hyperglycemia Induces Apoptosis of Human Pancreatic Islet Endothelial Cells

Effects of Pravastatin on the Akt Survival Pathway

Pancreatic islet microendothelium and β cells exhibit an interdependent physical and functional relationship. In this study, we analyzed the effect of chronic hyperglycemia on human pancreatic islet microendothelial cells as well as the involvement of the phosphatidylinositol 3-kinase/Akt and nephrin pathways, interleukin-1β, and nitric oxide production. In addition, whether 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors can reverse the response to high-glucose conditions was investigated. Proliferation of purified islet microendothelial cells cultured under hyperglycemic conditions (28 mmol/L glucose) decreased compared to that of normoglycemic cells (from 12.7% after 2 days to 47.7% after 30 days, \( P < 0.05 \)). In parallel, apoptosis progressively increased from 7% after 2 days to 79% after 30 days in high glucose (\( P < 0.05 \)) concomitant with an early increase of caspase-3 activity. Intermittent hyperglycemia induced greater apoptosis than sustained hyperglycemia. Apoptosis was accompanied by a reduced p-Akt/Akt ratio and inhibition of nephrin tyrosine phosphorylation. Pravastatin (1 \( \mu \)mol/L) decreased apoptosis induced by high glucose or oxidized LDL and increased Akt phosphorylation. Hyperglycemia significantly increased the production of the proinflammatory cytokine interleukin-1β and stimulated the expression of inducible nitric oxide synthase and the production of nitric oxide, possibly relevant to β cell mass and function. Thus, chronic hyperglycemia reduces islet microendothelial cell survival by inhibiting the serine-threonine kinase Akt pathway, and the effect of pravastatin on this pathway represents a potential tool to improve islet vascularization and, indirectly, islet function. (Am J Pathol 2008, 173:442–450; DOI: 10.2353/ajpath.2008.080238)

The pancreatic endocrine vasculature exhibits distinctive functional and structural features, which render them highly adapted to communicate with the underlying endocrine tissue in a cross-talk relationship. This notion stands against the background that the microvasculature has a key role at the interface between the vascular space and organ parenchymas and participates in numerous pathophysiological processes. Pancreatic islets are one of the most vascularized organs,\(^1,2\) and vascular endothelial growth factor-A secreted by the neighboring β cells is responsible for this strong vascularization and capillary fenestration from organogenesis to adult life.\(^3\)

Recent studies indicate that the islet vasculature is likely to play a role in the physiology as well as in the disease of the pancreatic islets. Besides providing oxygen, nutrients, and secretory signals from other cells to endocrine cells,\(^4\) producing a number of vasoactive, angiogenic substances, cytokines, and growth factors,\(^5\) islet endothelium has been shown to induce insulin gene expression during endocrine tissue development,\(^6\) to affect adult β cell function and to promote β cell proliferation. These effects are mediated by secretion of unknown paracrine signals that may include the hepatocyte growth factor,\(^7\) collagen IV, and laminins.\(^8,9\) Importantly, the islet endothelium is involved in the rapid transendothelial release of secreted insulin into the circulation,\(^2\) and it is suggested to have a role in fine-tuning blood glucose sensing and regulation.\(^3,10–13\) Studies in mice with pancreatic deletion of vascular endothelial growth factor-A or in murine models of type 2 diabetes indicate that morphological changes in islet vasculature are accompanied by changes in islet function.\(^6\)

by defective blood glucose levels and impaired glucose-stimulated insulin secretion, which play a key pathogenic role in the development of diabetes.\textsuperscript{3,13,14} Such endothelial disruption and metabolic abnormalities might involve the transmembrane signaling protein nephrin, specifically expressed in human pancreatic islet microvascular endothelial cells (MECs).\textsuperscript{10}

Collectively, these data indicate that a normal capillary network is essential for optimal β cell secretory function and blood glucose regulation. Several studies demonstrated that hyperglycemia induces early endothelial dysfunction on cultured micro- and macrovascular endothelium, characterized by changes in proliferation, barrier function, sensitivity to apoptosis and adhesion, and angiogenic and synthetic properties of endothelial cells.\textsuperscript{15–20} However, studies on islet-derived endothelial cells are lacking. In the light of the endothelial-endocrine axis within adult pancreatic islets, it is conceivable that hyperglycemia may induce alterations in islet endothelium, potentially contributing to the progressive reduction of \( \beta \) cell function and mass that characterizes the natural history of type 2 diabetes.\textsuperscript{21,22}

In the present study, we analyzed the in vitro effects of acute and chronic hyperglycemia on human pancreatic islet MECs. The effects of hyperglycemia on cell survival, Akt and nephrin phosphorylation, and interleukin (IL)-1β and nitric oxide (NO) production were evaluated. In addition, we investigated whether the 3-hydroxy-3-methylglutaryl coenzyme A inhibitor pravastatin, which is known to modulate phosphatidylinositol 3-kinase (PI3K)/Akt pathways and improve vascular function,\textsuperscript{23,24} may reverse the response of islet MECs to high-glucose conditions.

**Materials and Methods**

**Islet Endothelial Cell Culture Conditions**

Islet MECs were cultured onto endothelial cell attachment factor (Sigma Aldrich, Milano, Italy) coated tissue culture plates in endothelial basal medium with the EGM-bullet kit (Clonetics, San Diego, CA) containing 5.6 mmol/L glucose, with 20% fetal calf serum, 10 mmol/L L-glutamine, and antibiotics.\textsuperscript{25} Cells were grown until confluent, washed twice with Hanks’ balanced salt solution, and dispersed with trypsin/EDTA when subcultured in appropriate flasks or plates, depending on the experiment performed. When cultured under high-glucose conditions, complete medium was adjusted to 14 mmol/L or 28 mmol/L glucose (Sigma) to assess the diverse effects of glucose concentration and treatment duration. Medium was changed every 48 hours and experiments were always conducted in parallel with the physiological (5.6 mmol/L) concentration of glucose. All other experiments were performed using the glucose concentration of 28 mmol/L on the basis of these and previous studies.\textsuperscript{18–20}

To evaluate the effect of intermittent hyperglycemia on islet MECs, cells were subjected to repeated cycles of 48 hours of growth in high glucose, alternating with 48 hours of growth in normal glucose. Staining for expression of endothelial marker von Willebrand’s factor by immunofluorescence technique was performed as described.\textsuperscript{10} For long-term culture in high-glucose conditions, an SV40-immortalized human cell line established from purified islet MECs was also used; these immortalized cells have been shown to retain their phenotypic and functional characteristics.\textsuperscript{25}

Glucose uptake was assessed by a fluorimetric method, using a commercially available kit (Amplex Red glucose, Invitrogen, Milan, Italy) following the manufacturer’s instructions. Cell proliferation was assessed by trypan blue exclusion cell count and by measuring DNA synthesis by 5-bromo-2’-deoxyuridine incorporation colormetric immunoassay, using a commercially available kit (cell proliferation ELISA, 5-bromo-2’-deoxyuridine assay, Roche Diagnostics, Mannheim, Germany), following the manufacturer’s instructions. Five separate experiments at different time points during different culture conditions were performed, each in triplicate. Data were expressed as percentage change between cells grown at 28 mmol/L glucose versus cells grown at 5.6 mmol/L glucose (mean Abs\( _{450\text{nm}} \) islet MECs in high glucose/mean Abs\( _{450\text{nm}} \) MECs in physiological glucose X-100).

In experimental conditions with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, statins, cells were incubated with oxidized LDL (oxLDL), 100 μg/ml, for 24 hours at 37°C, as a proapoptotic and Akt-dephosphorylating stimulus.\textsuperscript{26} For preparation of oxLDL, 5 mg/ml LDL were mixed with 5 μmol/L CuSO\(_4\) and incubated for 18 hours at 37°C and oxidation was evaluated as previously described.\textsuperscript{26}

To evaluate the effects of statins on apoptosis, whether induced by high-glucose conditions or by oxLDL, and on Akt and nephrin dephosphorylation, islet MECs were treated with increasing doses of pravastatin (Calbiochem, Darmstadt, Germany) (0.1, 0.5, 1 μmol/L), on the basis of previous reports showing that the hydrophilic pravastatin at high concentration did not induce apoptosis compared to the lipophilic simvastatin.\textsuperscript{23,26} Three different conditions were assayed: pravastatin was given daily, or started after 4 days of high-glucose culture, or added overnight before cell collection.

**Detection of Apoptosis**

Apoptosis was evaluated in time course experiments at 3- to 6-day intervals by a photometric enzyme immunoassay measuring mono- and oligonucleosomes in the cytoplasmic fraction of cell lysates as an index of DNA fragmentation, which is, in turn, an early marker of apoptosis, using a commercially available kit (cell death detection ELISA\textsuperscript{PLUS}, Roche), following the manufacturer’s instructions. Further, islet MECs were also subjected to terminal deoxynucleotidyl transferase dUTP nick-end labeling assay analysis (ApopTag, Intergen Company, Purchase, NY), using vincristine (0.3 μg/ml) as a positive control for the induction of apoptosis. Cells were seeded onto 96-well plates, washed in phosphate-buffered saline (PBS), fixed in 1% paraformaldehyde in PBS, pH 7.4, incubated with TdT enzyme and digoxigenin-dNTP,
washed in PBS, and counterstained with anti-digoxigenin- fluorescein isothiocyanate antibody and with propidium iodide (1 μg/ml) in PBS. The fluorescein isothiocyanate-labeled DNA fragments in the apoptotic cells were visualized by inverted UV microscopy. Cells were counted by digital analysis (Windows MicrOlmage, version 3.4 CASTI Imaging, Venecia, I) of images obtained using a video camera (Leica DC100); positive apoptotic cells were expressed as a percentage of the total cells counted in 10× inverted microscope fields.

To confirm that apoptosis was occurring, activation of the caspase family was assessed by a caspase-3 colorimetric activity assay kit (Chemicon International, Temecula, CA), following the manufacturer’s instructions. Five to eight separate experiments at different time points during different culture conditions were performed, each in triplicate.

Immunoprecipitation and Western Blot Analyses

Islet MECs, subjected to different experimental conditions, were lysed at 4°C for 1 hour in lysis buffer. For the detection of nephrin contained within lipid raft microdomains the lysis buffer was supplemented with 20 mmol/L CHAPS 3-[(3-cholamidopropyl)-dimethylammonio-1-propanesulfonate] (Sigma). After centrifugation of the lysates at 15,000 × g, samples were normalized to 50 μg/sample in 20 μL and resolved by 8% sodium dodecyl sulfate-polyacrylamide gel electrophoresis under reducing conditions and transferred to nitrocellulose. Membranes were blocked and incubated with mouse monoclonal anti-phosphorylated Akt (p-Akt) Ab (Cell Signaling Technology, Beverly, MA) (1:1000) or with mouse monoclonal anti-Akt Ab (Upstate Biotechnology, Lake Placid, NY) (1:2000) overnight at 4°C. For nephrin detection, membranes were incubated with GP-N1 and GP-N2 polyclonal Ab (Progen Biotechnik GmbH, Heidelberg, Germany) (1:500) overnight at 4°C. Blots were then probed with peroxidase-conjugated goat anti-mouse IgG (1:5000) (Pierce, Rockford, IL) or protein A (Amersham, Buckinghamshire, UK) for 1 hour at room temperature and developed with chemiluminescence reagents (ECL, Amersham). Immortalized podocytes served as control cells. To detect phosphorylated nephrin, cell lysates were immunoprecipitated with an anti-nephrin IgG Ab, cross-linked to Sepharose-protein A, as described.

Three separate experiments, each in duplicate for each experimental condition, were performed. Data were expressed as p-Akt/Akt ratio and as phosphorylated nephrin following densitometric analysis of WB bands. Staining for the expression of nephrin was performed by immunofluorescence technique and detected using guinea pig anti-nephrin polyclonal GP-N1 and GP-N2 Ab, as described.

Further, the phosphorylation status of Akt was monitored by an ELISA assay, using a commercially available kit (cellular activation of signaling ELISA, CASE, Suparray Bioscience Corporation, DBA, Milan, Italy). Briefly, cells were seeded into a 96-well plate and fixed in 4% paraformaldehyde. One-half of the wells were treated with the anti-phosphoprotein specific primary antibody (1:150) and the other half with the anti-panprotein specific primary Ab (1:200) overnight at 4°C. Cells were then incubated with the secondary Ab (1:160) recognizing Akt regardless of its activation state for 1 hour at room temperature, and the amount of bound Ab was determined using a developing solution and an ELISA plate reader. The absorbance readings at 450 nm were normalized to relative cell number as determined by a cell staining solution. This assay was also used in experiments aiming to evaluate whether the effects of statin involved PI3K. In these experiments, islet MECs were treated with two unrelated PI3K pharmacological inhibitors, wortmannin (0.1 μmol/L) and LY294002 (10 μmol/L). Three to five experiments were performed for each experimental condition.

IL-1β, Nitric Oxide Synthases, and NO Detection

Cell culture supernatants were collected before each subculture and medium exchange, centrifuged and stored at −80°C. IL-1β was measured in duplicate by quantitative sandwich enzyme immunoassay (R&D Systems, Abingdon, UK), according to the manufacturer’s instructions. Color intensity was read at the appropriate wavelength on a microplate reader (Bio-Rad, Hercules, CA). Detection limit of the assay was 3.9 pg/ml.

For immunofluorescence detection of constitutive expression of nitric oxide synthase (eNOS) and inducible NOS (iNOS), cells were seeded onto eight-well chamber slides (Nalgene Nunc International, Rochester, NY) and cultured for 72 hours in normal or high glucose to subconfluence. Cells were fixed in 4% paraformaldehyde and permeabilized using 1% paraformaldehyde and 0.5% Triton X-100 for 10 minutes. After washing with PBS (0.25% bovine serum albumin), cells were then incubated with anti-human eNOS or with anti-human iNOS mAb (Transduction Laboratories, BD, Milan, Italy) (1:100) overnight at 4°C. Cells were washed and subsequently incubated with fluorescein isothiocyanate-conjugated anti-mouse IgG (Dako) for 1 hour at room temperature. After washing the slides were mounted in Vectashield H-1000 mounting medium (Vector Laboratories, Burlingame, CA) and examined by UV microscopy and digital images obtained using a low-light video camera. iNOSs were also detected by WB using the same mAbs to probe the membranes and as described above.

The cell-permeable NO reactive dye DAF2-DA (Alexis Italia, Vici, Italy) was used to examine intracellular production of NO under normal or high-glucose culture conditions, as described. NO was determined as nitrite concentration in culture supernatants by diazotization reaction, using NaNO2 as standard, as described.

Statistical Analysis

5-Bromo-2′-deoxyuridine incorporation, apoptosis (ie, optical density for DNA fragmentation assay and percentage of apoptotic cell for terminal deoxynucleotidyl transferase dUTP nick-end labeling assay), levels of p-Akt/Akt
expression, and levels of IL-1β and NO between cells grown in different glucose concentrations were compared using the Mann-Whitney U-test. Data were analyzed using the SPSS statistical package (SPSS, Chicago, IL), and P values less than 0.05 were considered significant. Due to batch-to-batch and interassay variations, in some experimental data are represented as percentages of variation (means ± SD) of the results obtained in 5.6 mmol/L glucose conditions within each experiment, unless otherwise stated.

Results

Cell Growth and Apoptosis

Under hyperglycemic culture conditions, islet MECs maintained the same morphological aspect of normal glucose counterparts (Figure 1, A and B) and the endothelial characteristics as assessed by detection of von Willebrand’s factor (Figure 1B, inset). Time course experiments showed that apoptosis, assessed by DNA fragmentation, was significantly higher in islet MECs cultured in 14 or 28 mmol/L glucose concentrations than in normal glucose starting from day 7 of culture. No significant difference was observed at day 2 of high-glucose culture nor between 14 and 28 mmol/L glucose concentrations (Figure 1C). Therefore, all subsequent experiments were performed using 28 mmol/L concentration. Glucose incorporation was increased, fluctuating from an increase of approximately 60 to 250% compared to that in normoglycemic conditions without showing particular temporal trends.

After 1 week culture in 28 mmol/L glucose, the number of viable cells detected by trypan blue exclusion was reduced to 65 ± 11% (n = 5) in respect to cells cultured in physiological concentration of glucose. In time course experiments, DNA synthesis assessed by 5-bromo-2′-deoxyuridine incorporation was progressively reduced in islet MECs grown in high glucose compared to physiological concentrations, decreasing from 13.5 ± 11% after 48 hours to 48 ± 14% after approximately 30 days of culture compared to normal glucose conditions (Figure 1D). The mean ± SD optical densities were 0.34 ± 0.1 in normal glucose, 0.27 ± 0.12 after 48 hours, 0.25 ± 0.13 after 7 days, 0.18 ± 0.04 after 14 days, and 0.12 ± 0.04 after 30 days in high glucose (P > 0.05 until 7 days and P < 0.05 afterward versus normal glucose conditions).

Apoptosis assessed by DNA fragmentation progressively increased in islet MECs grown in high glucose, ranging from an increase of 33 ± 28% after 48 hours up to an increase of 73 ± 48% after 30 days of culture compared to normal glucose conditions (Figure 1D). The mean ± SD optical densities were 0.28 ± 0.1 in normal glucose, 0.43 ± 0.3 after 48 hours, 0.44 ± 0.2 after 7 days, 0.6 ± 0.4 after 14 days, and 0.74 ± 0.5 after 30 days in high glucose (P > 0.05 at 48 hours and P < 0.05 afterward versus normal glucose conditions). Primary islet MECs in short-term experiments exhibited similar behavior in proliferation and apoptosis assays (data not shown).

Figure 1. Morphological aspects, proliferation, and apoptosis of islet MECs cultured in high glucose. Representative micrograph of islet MECs in normal (A) and high-glucose (B) culture. Original magnification, ×100. In high glucose, cells retain endothelial cell characteristics, ie, positive cytoplasm staining for von Willebrand’s factor, assessed by immunofluorescence (inset in B). C: Apoptosis, assessed as DNA fragmentation, of islet MECs cultured for 2, 7, or 14 days in 14 (gray columns) or 28 mmol/L glucose (black columns) compared to parallel culture in normal glucose (white column). D: Percentage of optical density variation of apoptosis, assessed by DNA fragmentation (closed circle) and proliferation, assessed as 5-bromo-2′-deoxyuridine incorporation (closed square) of cells in 28 mmol/L glucose, compared to cell in normal glucose (taken as 0). E: Percentage of apoptotic islet MECs subjected to terminal deoxynucleotidyl transferase dUTP nick-end labeling assay after culture in normal (NG) or in 28 mmol/L glucose (HG). Cells were incubated with vincristine (0.3 µg/ml) overnight as control. F: Assessment of caspase-3 activity in islet MECs incubated for up to 3 days in normal (NG) or 28 mmol/L glucose (HG). Data are expressed as means ± SD of five different experiments for each time point. *P < 0.05 compared to normal glucose culture.
The percentage of terminal deoxynucleotidyl transferase dUTP nick-end labeling-positive cells was similar (5 to 7%) in islet MECs incubated for 24 hours in normal or high-glucose conditions; by 72 hours, however, a significantly greater percentage of cells in high glucose were apoptotic (14 ± 5%, \( P < 0.05 \)), as shown in Figure 1E. An increase in caspase-3 activity, which is thought to be an early signal of apoptosis, was evident in islet MECs incubated with high glucose, with the highest results in the first 72 hours showing approximately a mean increase of activity of 115% (\( P < 0.05 \) versus normal glucose) (Figure 1F). In experimental conditions with intermittent hyperglycemia, islet MECs showed greater apoptosis, detected as DNA fragmentation, compared to parallel culture of sustained hyperglycemia (after 12 days of culture, means ± SD optical densities: 0.14 ± 0.1 for normal glucose, 0.42 ± 0.3 for sustained hyperglycemia, and 0.95 ± 0.4 for intermittent hyperglycemia, \( P < 0.05 \)) (Figure 2).

Expression of Phosphorylated Akt and Nephrin

Analysis of the Akt-dependent survival pathway by WB indicated that high-glucose conditions induced dephosphorylation of Akt, as demonstrated by the significant reduction of the p-Akt/Akt ratio (mean ratio 1.9 ± 0.6 for normal glucose, 0.8 ± 0.3 for all high-glucose cultures, \( P < 0.05 \)). The p-Akt/Akt ratio exhibited a trend of progressive decrease with the duration of high-glucose culture, as shown in Figure 3. Similarly, oxLDL induced dephosphorylation of Akt of islet MECs. By immunofluorescence microscopy on confluent monolayers of islet MECs in high glucose nephrin was detectable on the cell surface without evidence of nephrin loss or redistribution compared to normal glucose conditions, confirming previous observations \(^{10}\) (data not shown). However, WB analysis of the immunoprecipitates showed that hyperglycemia, although it did not reduce the expression of nephrin, inhibited its tyrosine phosphorylation (Figure 4), which has been shown to be a critical step in nephrin-induced signaling. \(^{30}\)

Pravastatin Inhibits the Effects of High Glucose and oxLDL on Islet MEC Apoptosis and Akt Activation

Exposure to the 3-hydroxy-3-methylglutaryl coenzyme A inhibitor pravastatin significantly inhibited apoptosis of islet MECs chronically (8 days) exposed to high glucose,
and apoptosis was induced by 100 \( \mu \text{g/ml} \) oxLDL (Figure 5). The effect of pravastatin was evident at the daily dose of 1 \( \mu \text{mol/L} \), with the lower concentration not having a significant effect (data not shown). The reduced apoptosis detected with pravastatin treatment was accompanied by an increase in the p-Akt/Akt ratio (Figure 6A). This effect increased with treatment duration, with an increase of the p-Akt/Akt ratio of 12% for 1 day of pravastatin treatment, 70% increase for 3 days treatment, and 130% increase for daily treatment when the cells were cultured for 8 days in high glucose (mean ratio 2.35 \( \pm \) 0.12 for normal and 1.17 \( \pm \) 0.2 for high-glucose culture, respectively, and 2.1 \( \pm \) 0.7 for all statin treatment regimes, \( P < 0.05 \)).

These results were confirmed by an Akt ELISA assay, which revealed a similar trend of the p-Akt/Akt ratio induced by high glucose, by oxLDL, and by pravastatin treatment (Figure 6B). The protective effect of pravastatin on Akt phosphorylation was reduced by overnight treatment of islet MECs with wortmannin and LY294002, suggesting that this effect was at least in part dependent on the activation of PI3K (Figure 6B).

### Levels of IL-1\( \beta \), NO, and NOS Expression

Production of IL-1\( \beta \), measured by ELISA on cell-free supernatants, was increased by 2 weeks of high-glucose culture (mean 17.3 \( \pm \) 7.6 pg/ml) compared to levels in supernatants of normal glucose culture (3.9 \( \pm \) 3.7 pg/ml) (\( P < 0.05 \)) (Figure 7A). By immunofluorescence staining, eNOS expression was detected in islet MECs in both culture conditions, while iNOS expression was detected only in cells grown in high glucose (Figure 7B). Similarly by WB analysis, only lysates of islet MECs in high glucose showed iNOS expression, whereas eNOS was expressed in normal glucose and up-regulated in high glucose (Figure 7C).

NO synthesis by islet MECs was investigated as the detection of DAF-2 DA fluorescence in a system of time lapse cinematography. As cells synthesize NO, they become detectable in the field. Under basal conditions, some cells were detectable with a fluorescence peak after 30 minutes followed by a rapid decrease; culture in high glucose induced a progressive increase in individual cells and in NO-dependent fluorescence intensity, persisting for many hours (Figure 7D). Mean values for repeated measurements of the stable NO oxidation product nitrite were significantly higher in supernatants of cells in high than in normal glucose (normal glucose, 3.5 \( \pm \) 1.5 nmol/L; 24 hours in high glucose, 5.2 \( \pm \) 1.8 nmol/L, \( P < 0.05 \); 2–7 days in high glucose, 38.9 \( \pm \) 20 nmol/L, \( P < 0.005 \)).

### Discussion

Pancreatic islet microendothelium exhibits unique structural and functional features in an interdependent physical and functional relationship with the neighboring \( \beta \)}
The presence of fluorescence was assessed by the abrogation of NO fluorescence in the field after 10 minutes, with fluorescence peak after 30 minutes followed by a rapid decrease. In high glucose, a progressive increase in the lightening of individual cells and fluorescence intensity was observed, with a peak approximately at 60 minutes; lightening persisted for up to 6 to 8 hours and decreased slowly. As positive control, cells were stimulated with NO-dependent generation of fluorescence by DAF2-DA in islet MECs. In addition, phosphorylation of the tyrosine sites (by Src family kinases) within the intracytoplasmic C terminal domain of nephrin activates mitogen-activated protein kinase (MAPK) and thereby the transcription factor activating protein-1 (AP-1). AP-1 modulates a variety of cellular programs, including proliferation, differentiation, and apoptosis.

The metabolic mechanisms by which hyperglycemia initiates apoptosis in vascular endothelium are incompletely understood. These mechanisms include oxidative stress, increased intracellular Ca$^{2+}$, mitochondrial dysfunction, changes in intracellular fatty acid metabolism, and impaired phosphorylation of the protein kinase Akt. The Akt signaling pathway plays a pivotal role in preventing apoptosis in a variety of settings and, in particular, Akt activation is crucial for the ability of factors such as insulin, insulin-like growth factor-1, and vascular endothelial growth factor to inhibit apoptosis in cultured endothelium. Recent data highlight its role also in insulin-mediated glucose transport and pancreatic β cell mass and function.

In the present study we observed that islet MECs under conditions of sustained hyperglycemia showed progressively reduced phosphorylation of Akt, suggesting an interference with the pathway(s) involved in Akt activation. Apoptosis of islet MECs and reduced Akt phosphorylation were induced also by treatment with oxLDL, known to affect the behavior of other endothelial cells and to play a major role in the pathogenesis of atherosclerosis. Concomitantly, in our study, hyperglycemia down-regulated the tyrosine phosphorylated form of the transmembrane protein nephrin without affecting its cellular expression or distribution. It is known that nephrin, once phosphorylated, associates with PI3K and activates the multifunctional Akt-dependent pathways. Therefore, hyperglycemia-induced apoptosis of islet endothelial likely involves the nephrin-mediated signaling cascade, as shown for human podocyte survival. In fact, nephrin appears to be more than a determinant of cellular ultrastructure, which, similarly to other adhesion molecules, might function in intracellular signal transduction. In addition, phosphorylation of the tyrosine sites (by Src family kinases) within the intracytoplasmic C terminal domain of nephrin activates mitogen-activated protein kinase p38 and jun kinase (JNK) and thereby the transcription factor activating protein-1 (AP-1). AP-1 modulates a variety of cellular programs, including proliferation, differentiation, and apoptosis.
Recent studies have linked the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, statins, and Akt, since Akt is a biological target for statin action in endothelial cells.\textsuperscript{23,26} Testing whether statins may reverse the response of islet MECs to oxLDL and hyperglycemia, we demonstrated that pravastatin treatment inhibited apoptosis and increased Akt phosphorylation. Akt is a major effector of the PI3K survival signaling pathway.\textsuperscript{44} In the present study, we observed that the protective effects of statin were blocked by treatment with pharmacological inhibitors of PI3K, thus suggesting the involvement of the PI3K/Akt-dependent pathway was impaired by hyperglycemia or oxLDL. These findings are in line with previous data showing that in endothelial cells, statins rapidly promote the activation of PI3K/Akt pathways, mediating cell survival, NO synthesis and migration, and improve vascular function independently from their lipid-lowering effects.\textsuperscript{23}

Moreover, the present report highlights that the effects of sustained hyperglycemia on islet vasculature could impair β cell function. The natural history of type 2 diabetes is in fact characterized by progressive increase in glucose levels, which has been claimed to be due to progressive reduction of β cells function and mass.\textsuperscript{21,22,45} The mechanisms causing this loss are still debated. Further, a major defect of insulin secretory function is found in all forms of diabetes,\textsuperscript{46} and sustained hyperglycemia has a detrimental impact on angiogenesis, growth, and function of transplanted islets.\textsuperscript{47,48} In this study we detected increased production of the proinflammatory cytokine IL-1β by islet MECs under hyperglycemic conditions. Previous studies demonstrated that human β cells are a potential source of glucose-induced IL-1β independently of any viral or immune-mediated process.\textsuperscript{49} IL-1β has been shown to impair insulin release in human islets and to induce Fas expression enabling Fas-mediated apoptosis, thus implicating an inflammatory process in the pathogenesis of glucotoxicity in the diabetic condition.\textsuperscript{40,50} Hyperglycemia also induced expression of the enzyme inducible NOS in islet MECs and increased NO production. This is in line with data in animal models indicating that islet microendothelium has a unique phenotype also in terms of expression of NO synthases, since their activities are closely regulated by glucose concentration.\textsuperscript{51} suggesting an organ-specific control of NO formation. The role of NO in islet cytotoxicity is well established\textsuperscript{29,52}; its role in the physiology of insulin release, although controversial, indicates that NO could directly impair insulin release.\textsuperscript{53}

At variance with other vascular endothelial cells, islet MECs express the barrier and signaling protein nephrin. Human and murine studies on glomerular filtration apparatus where nephrin is specifically located indicate that nephrin, when dephosphorylated, is associated with increased podocyte apoptosis and altered function.\textsuperscript{42,54} Nephrin dephosphorylation induced by hyperglycemia could therefore also impair islet vasculature function in addition to the effects on the PI3K-Akt pathway.

Due to the interplay between islet endothelium and β cells,\textsuperscript{1,2,31} the apoptotic effects of a diabetic milieu on islet MECs may carry additional relevant consequences to the endothelial cells. Among the islet vasculature functions serving the β cells there is, in fact, promotion of β cell proliferation.\textsuperscript{7–9} It is now accepted that postnatal β cell mass is dynamic and can increase, both in function and mass, to compensate for added demand, by replication and/or neogenesis.\textsuperscript{55} It remains to be elucidated how the islet microvasculature participates in sensing the environment of the islets and generates signals to affect adult islet endocrine function.

In conclusion, the data presented offer an insight into the pathological processes taking place within pancreatic endothelium in hyperglycemia. In this condition, in virtue of their participation in the endocrine tissue development and physiopathology, islet endothelial cells represent a target and an effector of hyperglycemic condition, actively contributing to progressive islet dysfunction. Statin treatment, by inhibiting apoptosis, represents a therapeutic tool to improve islet vascularization and, indirectly, islet function. Further investigations to understand the comprehensive role of endothelium in islet physiology and pathology are warranted.
