Adenosine is a potent modulator of inflammation and tissue repair. We have recently reported that activation of adenosine A$_{2A}$ receptors promotes collagen synthesis by human dermal fibroblasts and that blockade or deletion of this receptor in mice protects against bleomycin-induced dermal fibrosis, a murine model of scleroderma. Adenosine deaminase (ADA) is the principal catabolic enzyme for adenosine in vivo, and its deficiency leads to the spontaneous development of pulmonary fibrosis in mice. The aim of this study was to characterize further the contributions of endogenous adenosine and adenosine A$_{2A}$ receptors to skin fibrosis. Taking advantage of genetically modified ADA-deficient mice, we herein report a direct fibrogenic effect of adenosine on the skin, in which increased collagen deposition is accompanied by increased levels of key mediators of fibrosis, including transforming growth factor β1, connective tissue growth factor, and interleukin-13. Pharmacological treatment of ADA-deficient mice with the A$_{2A}$ receptor antagonist ZM-241385 prevented the development of dermal fibrosis in this model of elevated tissue adenosine, by reducing dermal collagen content and expression of profibrotic cytokines and growth factors. These data confirm a fibrogenic role for adenosine in the skin and reveal A$_{2A}$ receptor antagonists as novel therapeutic agents for the modulation of dermal fibrotic disorders. (Am J Pathol 2008, 172:1675-1682; DOI: 10.2353/ajpath.2008.070952)

Dermal fibrosis is a pathological hallmark of several disorders such as scleroderma or hypertrophic scar formation. Despite increasing efforts at investigating the mechanisms underlying fibrogenic processes in the skin, no effective antifibrotic therapy exists to date.

Adenosine is present in most biological fluids and is elevated during tissue stress, when it acts as a potent endogenous modulator of inflammation and tissue repair. The effects of adenosine are mediated through interaction with four G protein-coupled receptors, A$_1$, A$_{2A}$, A$_{2B}$, and A$_3$, which are expressed in a cell- and tissue-specific manner. We have recently reported that activation of the adenosine A$_{2A}$ receptor (A$_{2A}$R) promotes collagen synthesis by human dermal fibroblasts, and blockade or deletion of this receptor in mice protects against bleomycin-induced dermal fibrosis, a murine model of scleroderma.

Adenosine deaminase (ADA) is the main catabolic enzyme for adenosine in vivo. Its deficiency leads to marked increases in endogenous adenosine levels, which have been shown to be associated with the spontaneous development of pulmonary fibrosis in mice. The pulmonary fibrosis observed in these animals is accompanied by an increase in the number of myofibroblasts.
expression of profibrotic cytokines, and deposition of collagen.\(^6,7\)

To characterize further the contribution of endogenous adenosine and \(A_{2A}\)-Rs to skin fibrosis, we tested the hypothesis that chronic elevation of adenosine due to ADA deficiency leads to dermal fibrosis and that pharmacological blockade of these receptors could prevent the development of this fibrogenic process. We found that endogenously released adenosine plays an important role in the pathogenesis of skin fibrosis, promoting dermal fibrosis associated with elevated expression of profibrotic mediators including connective tissue growth factor (CTGF), transforming growth factor (TGF) \(\beta\), and interleukin (IL) 13. Pharmacological blockade of the adenosine \(A_{2A}\)-R prevented the development of dermal fibrosis in this mouse model of elevated tissue adenosine. These data confirm that the adenosine \(A_{2A}\)-R is a key player in dermal fibrogenesis, and adenosine \(A_{2A}\)-R antagonism may be a novel therapeutic target in the treatment of dermal fibrosing disorders.

**Materials and Methods**

**Reagents**

ZM-241385 was purchased from Tocris (Ballwin, MO). Tissue protein extraction reagent (T-PER) and bicinchoninic acid (BCA) protein assay kit were from Pierce Biotechnology (Rockford, IL). Mouse IL-13, IL-6, and TGF-\(\beta\)1 enzyme-linked immunosorbent assay (ELISA) kits were purchased from R&D systems (Minneapolis, MN). Polyclonal antibodies for CTGF and \(\alpha\)-smooth muscle actin (SMA) were obtained from Abcam (Cambridge, MA). Polyclonal antibody for platelet-derived growth factor (PDGF)-A was purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Goat anti-rabbit immunoglobulins and Fast Red substrate system were from DAKO (Carpinteria, CA). Dulbecco’s modified Eagle’s medium, penicillin-streptomycin, and fungizone were purchased from Invitrogen (Grand Island, NY) and all other reagents were from Sigma (Saint Louis, MO).

**Mice**

ADA-deficient mice were generated and genotyped as described previously.\(^8\) Mice homozygous for the null \(Ada\) allele were designated ADA-deficient (ADA-KO), whereas mice heterozygous for the null \(Ada\) allele were designated as ADA control (wild-type) mice (ADA-WT). ADA-KO mice exhibit a total loss of ADA enzymatic activity,\(^9\) whereas ADA-WT mice heterozygous for the null \(Ada\) allele have no phenotypic or metabolic differences from mice without the allele because one \(Ada\) allele or 50% ADA activity is sufficient to prevent any accumulation of adenosine or deoxyadenosine.\(^6,9\) All mice were on a 129sv/C57BL/6J mixed background, and all genotype comparisons were performed among littermates. Animal care was performed in accordance with Institutional Animal Care and Use Committee of NYU School of Medicine and National Institutes of Health guidelines. All experiments were performed in male mice, since we have previously observed that breaking tension and hydroxyproline content were greater in the skin of male C57/BL6 mice than their female counterparts, in agreement with findings by other investigators.\(^10\)

**Experimental Design: ADA Therapy and Administration of Adenosine \(A_{2A}\) Receptor Antagonist to ADA-Deficient Mice**

Polyethylene glycol-conjugated ADA (PEG-ADA) was prepared as described previously.\(^11\) ADA-KO mice received i.p. injections of PEG-ADA on postnatal days 1, 4, 8, 12, 16, and 20 (0.625, 1.25, 2.5, 2.5, 2.5, and 5 U, respectively; 1 U is defined as the amount necessary to convert 1 \(\mu\)mol/L of adenosine to inosine/min at 25°C). After the last injection, ADA-KO mice were maintained without PEG-ADA for 14 days and then sacrificed. ADA-WT mice were sacrificed at the end of the experimental period (34 days old). To determine the role of the adenosine \(A_{2A}\)-R, ADA-KO mice were treated with the \(A_{2A}\)-R antagonist, ZM-241385 (50 mg/kg b.i.d. administered in vehicle i.p.: 15% dimethyl sulfoxide, 15% Cremophor EL, and 70% water, in a total injection volume of 0.1 ml) for the last 8 days before sacrifice, and were compared to ADA-KO male mice.

**Morphometric Dermal Measurements**

Mice were sacrificed at the end of the experimental period. The backs of the animals were shaved before morphometric measurements. Skin-fold (pinch) thickness was measured using skin calipers on four different areas over the backs of mice. Skin thickness was measured on 6-mm punch biopsies obtained from the back. Breaking strength of the skin was measured on the 6-mm punch biopsies using a tensiometer (Mark-10 Series EG Digital Force Gauge, Mark-10 Corporation Copiague, NY), and the point of maximal stress before tearing of the biopsy was recorded, as we have previously reported.\(^5\) These studies were approved by the Institutional Animal Care and Use Committee of New York University School of Medicine.

**Immunohistochemistry**

After deparaffinization and rehydration of 5-\(\mu\)m thick tissue sections, antigen retrieval was performed for 15 minutes at 98°C with 0.01M citrate buffer, pH 6.0. To block nonspecific binding, the slides were incubated for 30 minutes with 5% normal goat serum in Tween 20 Tris buffered saline (TTBS: 20 mmol/L Tris-HCl, pH 7.4, 150 mmol/L NaCl and 0.1% Tween 20). Primary antibody (anti-CTGF 1/100 or anti-\(\alpha\)-SMA 1/100) in TTBS containing 1.5% normal goat serum was incubated overnight at 4°C. After washing, sections were incubated with an alkaline phosphatase-conjugated goat anti-rabbit IgG (1/200) in TTBS containing 1.5% normal goat serum, for 60 minutes at room temperature. Fast Red substrate system
ELISA Measurements

Skin biopsies were lysed in T-PER tissue protein extraction reagent. Total protein was determined spectrophotometrically by BCA assay kit, using bovine serum albumin as standard protein. Mouse IL-13, IL-6, and total and active TGF-β1 levels in skin lysates were determined by quantitative sandwich enzyme immunoassay technique following manufacturer instructions. Results were expressed as picograms per mg of protein.

Western Blotting

Skin homogenates (15 μg protein/lane) were electrophoresed (4 to 20% SDS Tris-Glycine) and transferred onto nitrocellulose membranes. The nitrocellulose membranes were blocked for 2 hours at 4°C in blocking solution (3% BSA in 1× TTBS). After blocking, the membranes were incubated with primary antibody (1:1000 dilution for CTGF, 1:1000 for α-SMA, 1:1000 for PDGF-A, and 1:5000 for β-actin) and incubated for 2 hours at 37°C with gentle shaking on a platform shaker. After incubation with secondary antibody, proteins were visualized using the enhanced chemiluminescence kit (Amersham Biosciences, UK). Band intensities were analyzed by Adobe Photoshop Software program (version 7.0.1) and normalized to β-actin level.

Quantification of Dermal Hydroxyproline Content

Hydroxyproline content in tissue specimens was measured colorimetrically as described previously, with modifications.12 Tissue specimens were dried and hydrolyzed in 6 N HCl at 110°C for 24 hours. Hydrolysates were filtered and neutralized to pH 7 with NaOH. 200 μl of each sample were mixed with 500 μl of chloramine-T solution (1.4% chloramine-T, 10% N-propanol, and 80% citrate-acetate buffer). The mixture was incubated for 20 minutes at room temperature. 500 μl of Ehrlich’s solution was added and the samples were incubated at 65°C for 18 minutes. Absorbance was measured at 560 nm. Standard curves (0 to 10 μg) were generated for each experiment using reagent hydroxyproline as a standard. Results were expressed as μg of hydroxyproline per mg of tissue.

Quantification of Adenosine Levels by High-Pressure Liquid Chromatography

Skin biopsies were washed in PBS containing antibiotics (penicillin 200 U/L, streptomycin 200 μg/mL, and fungizone 50 μg/mL), cut into small pieces, and incubated in DMEM (containing same antibiotics concentration as before) at 37°C, 5% CO2. After 4 hours of incubation, supernatants were collected and adenosine was extracted and quantitated by high-pressure liquid chromatography as previously described.13 Results were expressed as picomoles of adenosine per mg of tissue.

Statistics

Results are represented as mean ± SEM Data were analyzed by one-way analysis of variance and post hoc analyses of significance of differences between groups was determined by Bonferroni’s multiple comparison tests. All statistical analyses were performed with GraphPad Prism software v. 4.02 (GraphPad Software Inc., San Diego, CA).

Results

Skin Adenosine Levels Are Increased in ADA-Deficient Mice

It has been previously shown that ADA-deficient mice have increased adenosine levels in lung that are associated with spontaneous development of pulmonary fibrosis. To determine whether dermal levels of adenosine are increased in ADA-KO mice, skin was collected after the experimental period and incubated for 4 hours. Supernatants from ADA-KO mice skin, as well as from their WT littermates were analyzed by high-pressure liquid chromatography. As expected, adenosine concentrations were significantly higher (12.4 ± 1.2-fold increase, P < 0.01, n = 5) in ADA-KO mice as compared with ADA-WT mice (Figure 1).

Figure 1. Adenosine levels are increased in skin of ADA-deficient mice. Skin biopsies were cut and incubated for 4 hours at 37°C, 5%CO2. Culture supernatants were concentrated, and adenosine levels were assessed by high-pressure liquid chromatography. Shown here are differences in adenosine levels between ADA-deficient mice (ADA-KO) and their wild-type littermates (ADA-WT). P < 0.01, n = 5 per group.
ADA-Deficient Mice Exhibit Dermal Fibrosis with Increased Collagen Content

To characterize the skin phenotype of ADA-KO mice, we performed morphometric analyses at the end of the experimental period. Interestingly, ADA-KO mice showed significant increases in dermal thickness, skin-fold thickness, and breaking tension (128.7 ± 2.0%, 140.6 ± 2.8%, and 136.8 ± 5.3% of control, respectively, P < 0.001 for all) as compared with ADA-WT mice (Figure 2A–C). Hematoxylin & eosin staining of paraffin-embedded skin sections also corroborates the increase in ADA-KO dermal thickness, as shown in Figure 2E. There is greater collagen accumulation in the dermis of ADA-KO mice compared with the WT mice, as shown by picrosirius red staining (Figure 2E). Finally, dermal hydroxyproline content, another marker of collagen content, was increased by 57.8 ± 2.8% (n = 5, P < 0.001) in ADA-KO mice (Figure 2D).

Profibrotic Mediators Are Elevated in ADA-Deficient Mice

TGF-β1 plays a major role in connective tissue remodeling, scarring, and fibrosis.14 In addition to TGF-β1, other pro-fibrogenic cytokines such IL-13 stimulate fibroblast collagen production by different signaling mechanisms and are involved in the development of many fibrotic disorders.15 To investigate if these profibrotic cytokines were involved in adenosine-mediated dermal fibrotic development, we measured levels of TGF-β1 and IL-13 in skin homogenates by ELISA. Interestingly, IL-13 levels were significantly augmented in skin homogenates from ADA-KO mice (73 ± 15% increase over ADA-WT, P < 0.01, n = 5) (Figure 3A). TGF-β1 levels were also increased in ADA-KO mice skin homogenates as compared with ADA-WT mice (1.9 ± 0.3-fold increase, P < 0.05, n = 5) (Figure 3B). Various studies have also described a role for IL-6 in tissue remodeling and fibrogenesis, showing a direct correlation between IL-6 expression and fibrosis in skin16 and other tissues.17 Furthermore, improvement in skin fibrosis in systemic sclerosis is associated with decreases in IL-6 production.18,19 We have determined IL-6 expression in skin homogenates by ELISA and found increased cytokine levels in the ADA-KO mice as compared with the ADA-WT mice, although the difference was not statistically significant (Figure 3C).

CTGF is another key mediator of fibrosis because it promotes matrix deposition and fibroblast proliferation and is overexpressed in fibrotic lesions of scleroderma patients.20 It has been shown that CTGF is induced by TGF-β1 and is considered a downstream mediator of
some effects of TGF-β1 on fibroblasts. As ADA-KO mice overexpressed TGF-β1 in the skin, we investigated a potential correlation with CTGF levels. Immunohistochemistry revealed a significant sixfold increase in CTGF expression in ADA-KO skin as compared with ADA-WT skin (7.1 ± 0.8% vs. 1.2 ± 0.3% CTGF staining per total skin area, ADA-KO versus ADA-WT, n = 5, P < 0.01) (Figure 4A–B). Abundant distribution of CTGF in the skin of ADA-KO mice was observed particularly in the epidermis, dermal cells, and along hair follicles. Western blot analysis corroborated this pattern, as shown in Figure 4C (190.1 ± 15.3% increase in ADA-KO vs. ADA-WT mice, n = 5, P < 0.05).

α-SMA-expressing myofibroblasts are considered to be a major cellular component of pathological fibrosis, and an elevated number of these cells is present in fibrotic lesions. Consistent with the described dermal fibrotic manifestations, α-SMA-positive cells were more abundant in ADA-KO skin (96 ± 0.08% vs. 61 ± 0.08% staining per skin area, ADA-KO versus ADA-WT, n = 5, P < 0.01), as determined by immunohistochemistry (Figure 5A–B). This result was further confirmed by Western blot analysis (Figure 5C), where α-SMA expression was increased in ADA-KO as compared with ADA-WT mice (177.5 ± 31.6%, n = 4, P < 0.05).

It has been reported that the expression of PDGF and its receptors are increased in scleroderma patients. In particular, PDGF-AA has been implicated in fibroblast proliferation and its expression is up-regulated by IL-13. As shown in Figure 6, we analyzed the expression of PDGF-AA on skin homogenates by Western blot and found a significant increase in ADA-KO mice as compared with ADA-WT mice (145.2 ± 15.3% increase, P < 0.05, n = 4).

### Adenosine A2AR Antagonism Diminishes Dermal Fibrosis and Production of Profibrotic Mediators in ADA-Deficient Mice

We have previously shown that pharmacological blockade or genetic deletion of the A2AR protects against bleomycin-induced dermal fibrosis. To determine whether the adenosine A2AR antagonist ZM241385 (ZM, 50 mg/kg/day, i.p.) for 8 days before sacrifice. Dermal thickness, skin-fold thickness, and dermal breaking strength were reduced in ZM-treated ADA-KO mice as compared with ADA-KO mice (27.2 ± 8.3%, 21.7 ± 7.4%, and 48.9 ± 14.1% decrease, respectively, n = 5, P < 0.05) (Figure 2A–C). Furthermore, dermal hydroxyproline content was also decreased (61.4 ± 13.5%, n = 5, P < 0.001) (Figure 2D). These results correlate with histological sections that showed decreased dermal thickness as well as reduced collagen density when compared
with ADA-KO mice (Figure 2E). ZM-treatment of ADA-WT mice showed no statistically significant difference on morphometric parameters (dermal thickness, skin-fold thickness, and breaking tension) or in hydroxyproline content as compared with ADA-WT mice (Table 1).

Interestingly, the fibrogenic cytokines IL-13 and TGF-β, were reduced by 34 ± 8% (*P* < 0.05) and by 36 ± 8% (*P* < 0.05) (Figure 3), respectively, as a result of the A2aR antagonist treatment, suggesting that the over expression of these cytokines in the skin of ADA-KO mice is mediated in part through the A2aR.

When we investigated the effects of A2aR blockade on CTGF expression by immunohistochemistry, we found a significant decrease (52 ± 7% decrease, *n* = 5, *P* < 0.01) compared to ADA-KO mice (Figure 4A–B) that was further confirmed by Western blot analysis (38.6 ± 7.2% decrease, *n* = 4, *P* < 0.05) (Figure 4C). A similar pattern was observed regarding α-SMA expressing myofibroblasts, since A2aR antagonist treatment reduced positive-stained cells by 31 ± 4% compared to nontreated ADA-KO mice (*n* = 5, *P* < 0.01) (Figure 5A–B). Western blot analysis also confirmed this finding (39.7 ± 6.1% decrease, *n* = 4, *P* < 0.05) (Figure 5C) previously assessed by immunohistochemistry.

Finally, A2aR antagonist treatment of ADA-KO mice reduced PDGF-A expression (26.3 ± 5.1%, *n* = 4, NS) without affecting basal levels on ADA-WT mice. Taken together these findings confirm an important role for the A2aRs in the development of dermal fibrotic conditions.

![Figure 5](https://example.com/figure5.png)

**Figure 5.** a smooth muscle actin positive cells are increased in skin sections of ADA-deficient mice and normalized by A2aR antagonist treatment. A: Immunohistochemistry was performed to identify α-SMA-positive cells on skin sections, and photomicrographs were taken at original magnification ×400. B: Computerized image analysis was used to quantify α-SMA staining in sections among the different groups. *(P < 0.01, *n* = 5 per group)*. C: Western blot analysis of skin homogenates was performed to corroborate differences on α-SMA expression and a representative immunoblot is shown.

### Discussion

The experiments reported here were undertaken to investigate further the role of adenosine and adenosine A2aRs in skin fibrosis. We demonstrated that elevated tissue adenosine levels lead to fibrosis of the skin, as was spontaneously manifested in ADA-deficient mice. Increases in collagen, myofibroblasts, as well as the production of profibrotic mediators, characterize the skin phenotype of the ADA-deficient mice. Furthermore, treatment with an A2aR antagonist effectively reduced collagen accumulation and fibrogenic biochemical and cellular markers in this adenosine-mediated fibrotic model.

The profibrogenic role for adenosine shown here is consistent with previous reports by our group and others, however, the mechanisms that lead to adenosine-mediated fibrosis remain to be completely dissected. Montesinos and colleagues have demonstrated that occupancy of adenosine A2aR promotes wound healing in a murine model, in part by accelerating matrix deposition.24,25 A direct stimulation of collagen synthesis has been also demonstrated in human dermal fibroblasts through an A2aR/mitogen-activated protein kinase kinase-1/mitogen-activated protein kinase-mediated pathway.26 Furthermore, Chunn and colleagues have reported that elevated lung adenosine levels are associated with

A2aR antagonist ZM-241385 was administered to ADA-WT for 8 days (50 mg/kg/day), and morphometric measurements and hydroxyproline content were determined at the end of the experimental period. No statistical difference was found between ADA-WT (*n* = 5) and ZM-treated ADA-WT mice (*n* = 3).
spontaneous development of pulmonary fibrosis in ADA-deficient mice.\(^6,7\)

Interestingly, a correlation between plasma ADA activity in scleroderma patients and stage of the disease has previously been demonstrated.\(^26\) However, direct effects of elevated tissue adenosine have not been studied in the skin. It is possible that the increase in adenosine deaminase activity is an adaptive mechanism to counteract the sclerosing properties of circulating and tissue adenosine in this disease. Alternatively, the inflammatory environment is conducive to the up-regulation of anti-inflammatory influences such as adenosine, thus providing a potential link between the control of inflammation and fibrous tissue deposition in the skin.

IL-13 is a pleiotropic cytokine implicated in many fibrotic disorders. Whether IL-13 induces fibrosis by a TGF-\(\beta\)-dependent or -independent mechanism remains controversial.\(^27-29\) In our studies, we found that elevations in skin adenosine concentration stimulate secretion of both cytokines. Interestingly, ADA-deficient mice have been shown to secrete elevated levels of IL-13 in lung, and IL-13 transgenic mice have elevated levels of lung adenosine.\(^30\) In addition, adenosine has been reported to directly induce IL-13 expression in mast cells through activation of A\(_{2A}\)R.\(^31\) However, when we treated ADA-deficient mice with an A\(_{2A}\)R antagonist, levels of IL-13 were significantly reduced, indicating a role for A\(_{2A}\)R in regulating IL-13 production, either directly or indirectly.

With regard to TGF-\(\beta\), it is worth mentioning that adenosine has been shown to up-regulate TGF-\(\beta\) mRNA in hepatic stellate cells\(^32\) and both protein and message levels of TGF-\(\beta\) are overexpressed in the lungs of ADA-deficient mice.\(^6,7\) which are reduced with A\(_{2B}\) antagonist treatment.\(^33\)

Although the roles of different adenosine receptors in fibrosis remain controversial, it is likely that adenosine-mediated mechanisms of fibrosis are tissue specific and although common mechanisms exist, patterns of expression of adenosine receptors may differ from one organ to the other, influencing the overall effects of adenosine. In fact, deletion of A\(_{2A}\)R in ADA-deficient mice provokes enhanced pulmonary inflammation,\(^34\) whereas we have demonstrated that loss of A\(_{2A}\)R prevents bleomycin-induced dermal fibrosis\(^5\) and CCl\(_4\)- and thioacetamide-mediated liver fibrosis.\(^35\) Thus, different tissues may respond differently to chronic elevations in adenosine levels.

CTGF is not generally expressed in normal fibroblasts or tissues and its secretion has been associated with pathogenic fibrotic processes such as scleroderma, where it functions in maintaining and enhancing the profibrotic actions of TGF-\(\beta\).\(^20\) In accordance with this phenomenon, CTGF expression is greatly increased in skin of ADA-deficient mice and almost undetectable in healthy skin of ADA-WT mice. A\(_{2A}\)R antagonist treatment reduced these levels, further suggesting adenosine receptor blockade's potential as therapy for ameliorating fibrotic disorders. In addition, the association between adenosine elevation and CTGF overexpression, as well as the protection mediated by A\(_{2A}\)R blockade, is novel. However it remains to be elucidated whether decreased CTGF is a consequence of reduced TGF-\(\beta\)1 expression, since CTGF is potently induced by TGF-\(\beta\)1 and has been described as a downstream effector of TGF-\(\beta\)1.\(^20\) but it has also been shown that constitutive overexpression of CTGF in scleroderma fibroblasts might be independent of TGF-\(\beta\)1 signaling\(^36\) and different mediators, such as endothelin-1, have been implicated in the induction of CTGF independently from the TGF-\(\beta\)1 ligand.\(^37\)

We found an increased number of myofibroblasts associated with elevated skin adenosine concentration, a phenomenon that was prevented by pharmacological blockade of A\(_{2A}\)R. The origin of the myofibroblast population in fibrotic lesions is still unclear, although TGF-\(\beta\)1, CTGF, and even IL-13 have been reported to activate differentiation of fibroblasts into \(\alpha\)-SMA expressing myofibroblasts.\(^38-40\) In addition, epithelial cells and fibrocytes have been suggested as precursors of myofibroblasts.\(^41\) Previous studies with ADA-deficient mice have also related adenosine and myofibroblast increments in lung.\(^7\)

The present results suggest that adenosine, and moreover, A\(_{2A}\)Rs play important roles in the development of dermal fibrosis, enhancing collagen deposition and dermal thickening directly and indirectly through stimulation of involved key profibrotic mediators such as TGF-\(\beta\)1, CTGF, and IL-13 and profibrotic cell mediators such as myofibroblasts. Our results suggest that adenosine is an orchestrator of the fibrotic process and thus pharmacological blockade of A\(_{2A}\)Rs may treat or prevent the chronic fibrotic state.
