Gender-Based Differences in Bleomycin-Induced Pulmonary Fibrosis

Mehnaz Gharaee-Kermani,* Kazuo Hatano,† Yasuhiro Nozaki,† and Sem H. Phan†

From the Departments of Internal Medicine* and Pathology,† University of Michigan Medical School, Ann Arbor, Michigan

The role of gender and sex hormones is unclear in host response to lung injury, inflammation, and fibrosis. To examine gender influence on pulmonary fibrosis, male and female rats were given endotracheal injections of either saline or bleomycin. Female rats showed higher mortality rates and more severe fibrosis than did male rats, as indicated by higher levels of lung collagen deposition and fibrogenic cytokine expression. To clarify the potential role of female sex hormones in lung fibrosis, female rats were ovariectomized and treated with either estradiol or vehicle plus endotracheal injections of either saline or bleomycin. The results showed diminished fibrosis in the ovariectomized, bleomycin-treated rats without hormone replacement. Estradiol replacement restored the fibrotic response to that of the intact female mice in terms of lung collagen deposition and cytokine expression, which was accompanied by higher plasma estradiol levels. Furthermore, fibroblasts from bleomycin-treated rats exhibited increased responsiveness to estradiol treatment, causing dose-dependent increases in procollagen 1 and transforming growth factor-β, mRNA expression relative to untreated controls. Taken together these findings suggest that female mice may have an exaggerated response to lung injury relative to male mice because of female sex hormones, which have direct fibrogenic activity on lung fibroblasts. This may provide a mechanism for a hormonally mediated intensification of pulmonary fibrosis. (Am J Pathol 2005, 166:1593–1606)

Idiopathic pulmonary fibrosis (IPF) is a chronic, progressive form of interstitial lung disease. The median survival rates are reported to be ~5 years, and most physicians consider it to be an ultimately fatal disease. In the United States, the mortality rate due to pulmonary fibrosis (PF) has increased from 40 to 56% between 1979 and 1991. PF is commonly characterized by some degree of lung inflammation and abnormal tissue repair, namely scarring, or the replacement of normal functional tissue with connective tissue. This process is now known to involve an intricate cytokine network that activates and mediates interactions between multiple cell types, resulting in the elevation of collagen gene expression and abnormal deposition of collagen in the lung.

To date, a variety of animal models have been used to investigate mechanisms of PF and other types of fibrosis, including bleomycin-induced pulmonary fibrosis (BLM-IPF) in rodents and other animal species. However, only a few studies have dealt with the role of gender in PF. In vivo studies have found that female hamsters immunized with trinitrochloro-1-benzene were more susceptible to the development of PF than males. In humans, studies of several diseases involving connective tissue diseases may indicate the importance of gender in fibrosis. The incidence of familial IPF is higher among females than males, according to an early study, and it has been reported that women are diagnosed with both diffuse PF and Hermansky-Pudlak syndrome more often than men. It has also been documented that female cystic fibrosis patients have a worse prognosis than do their male counterparts. Current evidence suggests that women develop alcoholic liver disease at lower levels of alcohol intake and throughout a shorter period of time as compared to men, thus making them more susceptible to alcohol-induced liver injury than are males.

With regard to the role of sex hormones on disease severity, much of the evidence suggests that the estrogen hormone, which is gender-specific, has a significant influence on disease progression. A significant increase in estradiol levels have been reported in the blood of female patients with alveolitis, histocytosis X, and lung...
sarcoidosis, with the magnitude of changes in hormone levels correlating with the severity of respiratory failure. Recently, topical estrogen has been found to be effective in wound healing in the elderly by alteration of inflammatory response and stimulation of matrix production, as shown by increased collagen deposition. In addition, a recent study has reported that administration of estradiol induced inflammatory response in the lateral prostate of castrated rats. Moreover immune reactivity is greater in females than males in both experimental animals and in humans. Thus sex hormones influence the onset and severity of immune-mediated pathological conditions by modulating lymphocytes, with immunoregulatory T cells appearing to be the most sensitive and responsive of the lymphoid cells to sex hormone exposure. In addition, it has been shown that estrogen can increase transforming growth factor (TGF)-β production by osteoblasts and other cells, and regulate apoptosis. However, despite this evidence, direct evidence linking gender, sex hormones, and lung disease remains lacking.

Objectives for this study were to explore the effects of gender and estradiol on lung fibrosis, and more specifically, to determine the mechanisms that enable estradiol to alter or intensify the fibrotic process. Using a well-characterized model of BLM-IPF in rats, the influence of both gender and estradiol on the progression of lung injury, inflammation, and fibrosis was analyzed using lung histopathology, cytokine expression, and collagen deposition in vivo, as well as by examination of morbidity and mortality rates. Whereas the gender study compared the response of male and female rats to BLM, the estradiol study compared the response of ovariectomized rats, with or without estradiol replacement therapy. The findings confirmed that female gender enhances lung fibrosis with female rats showing more extensive fibrosis, higher mortality rates, and significantly larger and more consolidated fibrotic lesions in response to BLM treatment. However ovariectomy diminished lung fibrosis, while estradiol replacement reversed this diminution. Furthermore, isolated lung fibroblasts from BLM-treated rats showed an altered phenotype as manifested by increased responsiveness to estradiol treatment, causing greater increases in procollagen 1 and TGF-β1 mRNA expression relative to untreated controls.

**Materials and Methods**

**Induction of PF and Tissue Sampling**

Specific pathogen-free, 3-month-old male and female Fisher 344 rats, weighing 180 to 200 g were obtained from Charles River Breeding Laboratories, Inc. (Wilmington, MA). These animals arrived in filtered cages, and were maintained in clean animal quarters separate from other laboratory animals. The rats were handled and maintained using microisolator techniques with daily veterinarian monitoring. The University of Michigan Committee on the Use and Care of Animals approved these experiments. Male and female rats were randomly chosen for the control or experimental groups. Seventy male rats were divided equally (14 per group) into five groups. An additional 70 female rats were also divided in the same manner. On day 0, half of the rats in each group were treated with 0.75 U/100 g body weight BLM (Blenoxane; Bristol-Myers Co., Evansville, IN) by endotracheal injection, as previously described. The remaining half received only sterile saline (SAL) endotracheally. Animals were examined daily, and body weights and survival rates recorded. One group each of the male and female rats were sacrificed under ketamine anesthesia on days 3 (group 1), 7 (group 2), 14 (group 3), 21 (group 4), and 28 (group 5) after BLM or SAL injection. At each time point, the lungs from three control and three experimental animals of each gender were used for extraction of RNA for Northern hybridization or polymerase chain reaction (PCR) analysis. From the remaining animals in each group, the lungs were rapidly dissected out and immediately inflated under 10 cm of pressure with phosphate-buffered saline (PBS) or 10% neutral buffered formalin, pH 7.2. After overnight fixation, lungs were embedded in paraffin. PBS-inflated lung tissues were used for frozen sections and used for immunohistochemistry. Serial sections (3 to 4 µm) of formalin-fixed tissue were used for routine histology and histochemistry. In addition, on day 21 after BLM challenge, lung tissue was harvested for analysis of fibrosis by hydroxyproline assay.

**Ovariectomy in Rats**

To clarify the relationship between female sex hormone and lung fibrosis, 78 3-month-old female Fisher 344 rats were used. Animals were divided equally into two groups, an ovariectomized group and a control group. The ovariectomy (OV) group underwent bilateral OV, and the sham or normal (N) operation group underwent a sham operation. When the hormonal status of the OV rats had stabilized at 3 weeks after OV, plasma estradiol levels were evaluated in all rats, and estradiol treatments commenced. The two groups were thus further divided equally into rats receiving estradiol (designated as +E) and those receiving vehicle (designated as +V) only.

**Exogenous Estradiol Treatment in Ovariectomized Rats**

Estradiol (17β-estradiol) was dissolved in propylene glycol and administered at 8 µg/kg/hour, a dose that will produce serum levels approximating those seen in vivo in rat pregnancy (258 pg/ml). After filling the drug into a pump (model 2004; Alza Corp., Palo Alto, CA), the pump was preincubated in PBS at 37°C for 24 hours. For control purposes, propylene glycol was administered at the same concentration as estradiol. Miniosmotic pumps were implanted into 1-cm subcutaneous pockets made in the nuchal area 3 weeks after OV for continuous delivery of estradiol or vehicle, with a group of OV and sham rats not receiving any estradiol or vehicle. Each group was then further divided into two equal groups receiving either endotracheal injections of SAL (indicated by +SAL) or BLM (indicated by BLM) 24 hours after implantation.
The eight groups of rats were then referred to as OV + BLM, N + BLM, OV + V + SAL, OV + V + BLM, OV + E + BLM, N + V + SAL, N + V + BLM, or N + E + BLM. On day 14 after BLM challenge, lung tissue and blood were harvested for analysis of fibrosis, histopathology, cytokine, collagen expression, and plasma estradiol levels, using immunohistochemistry, reverse transcriptase (RT)-PCR, and enzyme-linked immunosorbent assays. In addition, on day 21 after BLM challenge, similarly treated groups of rats were sacrificed for harvesting of lung tissue for analysis of fibrosis by hydroxyproline assay. Plasma estradiol levels were also measured from these rats. The entire experiment was repeated twice with similar results.

**Rat Lung Fibroblast Isolation and Culture**

Rat lung fibroblasts were isolated from days 7 and 14 BLM-treated (BRLF) or SAL-treated (NRLF) female lung tissue as previously described. Fibroblasts used in this experiment were between cell passages 2 and 4 after isolation. Semiconfluent fibroblasts were washed three times and treated for 24 hours with various concentrations of either estradiol or vehicle in fresh serum-free Dulbecco’s modified Eagle’s medium containing 0.5% bovine plasma-derived serum. After 24 hours, the cells were harvested for analysis of cytokine and collagen gene expression. Fibroblast proliferation was estimated by [3H] thymidine incorporation in 96-well plates. In addition, fibroblasts were grown on Lab-Tek 4 chamber slides (Nalge Nunc International, Rochester, NY) and treated as above and the cells were used for immunostaining.

**Lung Histopathology and Immunohistochemistry**

General histological appearance of lung tissue was assessed after routine hematoxylin and eosin (H&E) staining, whereas Masson trichrome staining was used for assessment of collagen deposition. Lung cell identification was performed by histochemical and immunohistochemical techniques as previously described. Eosinophils were identified by either staining with chromotrope 2R (stains eosinophil granules) as previously described or by immunostaining of frozen lung sections with BMK-13 antibody. Monocytes and macrophages were identified by their mononuclear morphology and by immunostaining with ED1 antibody. T lymphocytes were identified by staining with CD3 antibody. Immunostaining also was performed to determine the effects of estradiol on TGF-β1 and collagen expression by fibroblasts. Semiconfluent NRLFs and BRLFs stimulated with estradiol in the manner described above were stained with rabbit anti-TGF-β antibody at a concentration of 5 μg/ml (R&D Systems, Minneapolis, MN), and anti-collagen I antibody at 1:200 dilution (Cymbus Biotech, Flanders, NJ) by immunoperoxidase and immunofluorescence techniques.

**Hydroxyproline Assay**

To evaluate fibrosis, lungs were harvested from day 21 BLM-treated rats, homogenized, and assayed for hydroxyproline content as previously described.

**mRNA Analysis**

At the indicated time points, animals were sacrificed and the lungs rapidly perfused with sterile PBS via the right ventricle until blanched. The lungs were rapidly dissected out and promptly suspended in guanidine isothiocyanate solution. Total RNA was isolated from lung tissues or cultured fibroblasts, and the poly(A)-rich fraction purified by oligo (dT) cellulose chromatography as previously described. Northern hybridization analysis was used to determine and quantify lung fibrogenic cytokine (TGF-β1, MCP-1, TNF-α), procollagens α1 (I), and α1 (III) mRNA, as previously described. The sequences for the oligonucleotide anti-sense probes are shown in Table 2. The blots were reprobed with a GAPDH probe for use as internal control for normalizing the data. RT-PCR was undertaken as before, using primers for TGF-β1, MCP-1, procollagen α1 (I), interleukin (IL)-4, and interferon (IFN)-γ, plus GAPDH as a control (primer sequences shown in Table 2).

**Plasma Estradiol Assay**

Circulating estradiol levels were measured using a commercially available estradiol enzyme-linked immunoassay kit (catalog no. 58225; Cayman Chemical Co., Inc., Ann Arbor, MI) according to the manufacturer’s instructions.

Morphometric Analysis

The number of lung monocytes/macrophages, T lymphocytes, and eosinophils were counted in tissue sections stained with specific antibodies as previously described.\textsuperscript{12} Positively stained cells were counted by light microscopy using the $\times 40$ objective and an ocular grid. At least 30 randomly chosen, noncontiguous, and nonoverlapping high-power fields were counted in each lung segment. Five segments from each rat lung and a total of three to four rats per group were analyzed. Cell counts were expressed as the number of cells per high-power field. For determination of the number of TGF-$\beta$- and collagen-expressing cells in normal or fibrotic lung fibroblasts treated with estradiol or vehicle, the numbers of positively stained cells as well as the total number of cells were counted from 10 randomly chosen noncontiguous high-power fields. Three slides per group were analyzed and the results were expressed as the percentage of positively stained cells.\textsuperscript{25}

Statistical Analysis

All data were expressed as means $\pm$ SE, with $n$ being the number of animals for each group. Differences between mean values from the various treatments and control groups were assessed for statistical significance by analysis of variance, and if significant were followed by analysis using Scheffe’s test for comparison between any two groups.\textsuperscript{9–12} A $P$ value $<0.05$ was considered statistically significant.

Results

Effects of Gender on BLM-Induced Morbidity and Mortality

To determine the importance of gender in PF, male and female rats were treated with endotracheal injections of BLM or SAL on day 0. Animals were monitored daily for body weight and mortality rates were compared between male and female rats after BLM administration. Results showed that female rats had greater weight loss when compared to males ($30 \pm 1.0\%$ versus $20 \pm 1.1\%$) 2 to 3 weeks after BLM injection. Some of the female rats became very sick with severe respiratory distress as the disease progressed, resulting in respiratory failure and death. Females had a mortality rate of $80 \pm 5.3\%$, whereas all male rats survived at 3 weeks after BLM treatment. Thus, female gender appeared to enhance the effects of BLM treatment.

Effect of Gender on Lung Fibrosis

The amplitude of the lung fibrosis induced by BLM was determined by lung histopathology and lung hydroxyproline content. Examination of fixed lung tissue from day 7 treatment after BLM showed inflammation and early fibrotic lesions (Figure 1A). These became more extensive by day 14. Lungs from female rats had significantly larger and more consolidated fibrotic lesions with dramatic increase in overall lung cellularity at days 7 and 14 as compared to those from males. Chromotrope 2R staining revealed larger numbers of eosinophils and greater overall cellularity at day 7 female rats after BLM as compared to that in males (Figure 1A, a and b), with fibrotic lesions becoming more extensive and consolidated in females at days 14 and 21 than were observed in the males (Figure 1A; c to f and i to l). In contrast, none of the control lungs demonstrated significant morphological changes, showing no evidence of inflammation, eosinophil, or other inflammatory cell recruitment in either gender (Figure 1A; g, h, m, and n). The eosinophils were clustered in cellular areas where early fibrosis was evident (Figure 1A, arrows). Morphometric analysis of the lung tissue sections showed that significantly higher numbers of eosinophils in BLM-treated female lung tissue compared to that in the male (Figure 1B). ED-1 monocyte- and macrophage-positive cells were found within the alveolar septa and space and in larger numbers in female rat lung tissues compared to those in male tissues at day 7 after BLM treatment (data not shown). Masson trichrome staining of formalin-fixed tissue revealed greater and denser amounts of collagen deposition in female lung tissue at day 7 after BLM treatment compared to male lungs (data not shown), which became more extensive and apparent at days 14 and 21 in the female lungs, but still significantly less severe in male lungs (Figure 1A, i to l).

F, Forward or sense primer; R, reverse or anti-sense primer.
To confirm the morphological evidence of significant gender difference in lung fibrosis, female and male rat lung tissues from the day 21 (after BLM) time point were homogenized and assayed for hydroxyproline content. Consistent with the morphological findings, the results showed that female lungs had a significantly greater BLM-induced increase in total hydroxyproline content relative to that in male lungs (Figure 2). The lung hydroxyproline contents of control female and male rats treated with SAL only were not significantly different. These quantitative results confirmed the increased susceptibility of female rats to develop lung fibrosis in response to BLM-induced lung injury.

**Effects of Gender on BLM-Induced Lung Collagen Expression**

Previous studies have shown that endotracheal BLM administration in male rats causes rapid development of lung fibrosis, characterized by a transiently increased...
number of contractile, filament-laden parenchymal cells, increased lung collagen synthesis, and deposition. Because lung histopathology, collagen staining, and hydroxyproline data indicated greater BLM-induced lung collagen deposition in female relative to male rats, the effect of gender on lung collagen gene expression was examined. The amounts of lung procollagen \( \alpha_1 \) (I) and \( \alpha_1 \) (III) mRNA were analyzed by Northern blotting. Consistent with the histopathology and hydroxyproline analysis, the results showed significantly higher BLM-induced increases in \( \alpha_1 \) (I) mRNA in lungs of treated female rats after BLM between days 7 and 14 with subsequent gradual decline toward control levels, whereas the lesser increases in male rats appear to start earlier on day 3 and up to day 14 (Figure 3A). Quantitative analysis of the blots using a radioactivity imaging system and after normalization to the GAPDH signal, indicated peak increases of procollagen \( \alpha_1 \) (I) in BLM-treated female rats at days 7 and 14, which were significantly higher than those in male rats at the same time points, with a subsequent gradual decline toward control levels in lungs of either gender (Figure 3B). The control SAL-treated groups showed no significant differences between female and male lungs at any of the time points. Control hybridization with a GAPDH probe showed no significant variation in GAPDH mRNA (Figure 3A). A similar result was seen for up-regulation of lung collagen \( \alpha_1 \) (III) mRNA (data not shown).

Effects of Gender on BLM-Induced Lung Cytokine Expression

Previous studies have shown that several fibrogenic cytokines such as TGF-\( \beta_1 \), MCP-1, and tumor necrosis factor (TNF)-\( \alpha \) have potential roles in fibrosis in the lung and other organs. To quantitate expression of these fibrogenic cytokines, their mRNA levels in both female and male lung tissues were analyzed by Northern blotting. Consistent with the increased fibrosis in female versus male rats, the results showed significantly higher BLM-induced increases in TGF-\( \beta_1 \), MCP-1, and TNF-\( \alpha \) mRNAs in female versus male lungs (Figure 4). Quantitation of lung cytokine mRNAs showed significant up-regulation of TGF-\( \beta_1 \) mRNA in lungs of treated female rats after BLM between days 7 and 14 with peak increase at day 7, whereas up-regulation occurred in male rats between days 3 and 7 (Figure 4, A and B). MCP-1 mRNA was up-regulated between days 3 and 21 with peak increases on day 7 for both sexes, but the elevated levels were significantly higher in female rats versus male rats (Figure 4C). Up-regulation of TNF-\( \alpha \) occurred between days 3 and 14 in females, and between days 7 and 14 for males with peak increases on day 7 for both sexes, however the increase in female lungs was only statistically significant at the day 3 time point (Figure 4D). Control animals showed no significant changes in mRNA levels at any of the time points examined. As with the procollagen data, lung GAPDH mRNA levels were not significantly different at all time points in both SAL controls and BLM-treated animals (Figure 4A), and they were used for normalization of the results for the cytokine mRNA determinations.

Effects of Ovarian Dysfunction with Exogenous Estradiol Supplementation on BLM-Induced Morbidity and Mortality

Gender studies indicated that in response to BLM-induced lung injury, female rats had increased severity of disease and decreased survival rates compared to male rats. This may be related to the modulating effect of female sex hormones on processes related to the
fibrotic process. To clarify such a potential relationship between female sex hormones and lung fibrosis, the effects of OV with or without rescue with exogenous estradiol treatment were examined in female rats. Animals were monitored daily for body weight and mortality rates compared among all groups of rats after BLM administration. The results showed that whereas the ovariectomized rats receiving vehicle (OV/V/BLM) only had zero mortality at day 21 after BLM injection, the estradiol treated ovariectomized (OV/E/BLM) rats showed more severe disease and a 20 ± 1.2% mortality rate. Estradiol supplementation in sham-operated normal (N/E/BLM) rats also showed severe disease and comparable mortality rate. All saline (+SAL)-treated control groups exhibited zero mortality. Thus, estrogen appeared to enhance the effects of BLM treatment.

The Effects of Ovarian Dysfunction with Estradiol Supplementation on Lung Fibrosis

To assess the effects of OV and estradiol on lung fibrosis, histopathology was first assessed (Figure 5). Morphological evaluation on day 14 post-BLM treated lung sections showed a diminished fibrosis and lower numbers of monocytes, macrophages, and eosinophils in ovariectomized (OV + BLM) relative to sham-operated (N + BLM) rats (Figure 5, A and B). This diminution in ovariectomized rats was overcome by estradiol supplementation (OV + E + BLM rats) but not by vehicle (OV + V + BLM) rats as shown in Figure 5, C and D. Control lungs from all saline (+SAL)-treated groups did not demonstrate any significant morphological changes at the same time point (Figure 5, E and F). To appreciate the amplitude of lung injury and inflammation induced by BLM in all groups, the
number of inflammatory cells in lung tissue at day 14 after BLM administration was counted morphometrically. EDT-1-positive cells (monocytes and macrophages) were found within the alveolar septa and space and were counted as described in Materials and Methods. The results showed that the percentage of macrophages, monocytes, and eosinophils found within the alveolar septa and space and were counted as described in Materials and Methods. The results showed that the percentage of macrophages, monocytes, and eosinophils in lungs of ovariectomized rats treated with vehicle only (OV + V + BLM) was significantly lower than in the other BLM-treated groups (Table 3). In contrast, the number of lungs CD3-positive T lymphocytes in the OV + V + BLM group was greater than in lungs of rats in the OV + E + BLM and other groups (Table 3). Masson trichrome staining showed reduced collagen deposition in lungs of rats in the OV + V + BLM compared to the OV + E + BLM group (data not shown).

To obtain quantitative biochemical confirmation, hydroxyproline analysis of lung homogenates from all groups at day 21 after BLM challenge was undertaken. The results showed that the total lung hydroxyproline content of rats in the OV + V + BLM group was significantly lower than that in the OV + E + BLM and N + V + BLM groups (Figure 6A). This reduction in fibrosis in OV + V + BLM rats was accompanied by significantly reduced lung α1(1) procollagen mRNA levels at the day 14 time point when compared with the OV + E + BLM and N + V + BLM groups (Figure 6B). These results were consistent with the histological findings, thus confirming the role of the ovary and estradiol in the increased susceptibility of female rats to develop lung fibrosis in response to BLM.

**Effect of OV with Estradiol Supplementation on Plasma Estradiol Level**

On day 21 after OV, 3 weeks after BLM challenge, blood was collected and plasma estradiol levels were measured by enzyme-linked immunosorbent assay. Results showed a decrease in plasma estradiol levels after OV with return toward normal levels after implantation of mini osmotic pumps containing estradiol but not vehicle only (Figure 6C). Higher plasma estradiol levels in BLM-treated rats also showed higher lung hydroxyproline content (Figure 6D) and associated with higher mortality and morbidity rate.

**The Effects of Ovarian Dysfunction with Estradiol Supplementation on BLM-Induced Lung Cytokine Expression**

To identify relationships between estradiol and the ability to enhance expression of inflammatory and fibrogenic cytokines, lung TGF-β1, IL-4, MCP-1, and IFN-γ mRNA levels were examined by RT-PCR. The results indicated that there was a significantly reduced expression of TGF-β1 and IL-4 mRNA in ovariectomized (OV + V + BLM) rats relative to sham-operated controls (N + V + BLM) at day 14 after BLM treatment (Figure 7, A and B). This reduction in TGF-β1 and IL-4 mRNA levels in OV + V + BLM rats was accompanied by a significant reduction in TGF-β1 protein levels in the lungs of OV + V + BLM rats (Figure 7A).

OV, ovariectomy; N, normal sham-operated group; V, vehicle; E, estradiol.

*Significant differences *P* < 0.01 in values measured in bleomycin-treated group compared to the OV + V + bleomycin.
IL-4 mRNA expression in ovariectomized rat lungs was negated by estradiol supplementation (OV/H11001E/H11001BLM group), which was significantly higher than the levels in lungs of ovariectomized rats receiving vehicle only (OV/H11001V/H11001BLM group). However, the expression of MCP-1 was not significantly affected by OV with or without estradiol treatment (Figure 7C). In contrast to the effects on TGF-β1 and IL-4 expression, IFN-γ mRNA levels were increased by OV, which was reversed by estradiol supplementation (Figure 7D). Thus these results suggest that the female gender via estradiol can enhance the response to BLM-induced lung injury by enhancing the production of type 2 cytokines and collagen synthesis, but reducing the expression of IFN-γ.

**Effects of Estradiol on Fibrotic Lung Fibroblasts in Vitro**

In view of the *in vivo* importance of estradiol in affecting lung fibrosis, its ability to directly affect fibroblast function...
in vitro was examined. Rat lung fibroblasts isolated from BLM-treated (BRLF) and control (NRLF) rats were exposed to various concentrations of either estradiol or vehicle. The cells were then analyzed for collagen and cytokine mRNAs by RT-PCR. Estradiol treatment caused a dose-dependent increase in procollagen mRNA levels in BRLFs that peaked at 10 nmol/L (Figure 8A). Only slight increases in procollagen mRNA were noted in NRLFs, and these were significantly lower than those seen in BRLFs. This difference in responsiveness was also observed with respect to TGF-β1 and IL-4 mRNA levels. Thus relative to untreated control cells, estradiol treatment on BRLF caused a dose-dependent increase in these mRNA species that were significantly higher than the levels seen in similarly treated NRLFs (Figure 8, B and C). However, the expression of MCP-1 was not significantly affected by estradiol treatment. Thus estradiol appears to have a selective profibrogenic effect on isolated lung fibroblasts. These results demonstrated that estradiol could directly activate selective lung fibroblast functions and this may provide a mechanistic basis as to how female sex hormones may represent a risk factor for the development of more severe PF.

**Discussion**

There is evidence to suggest that gender affects the severity of lung disease, such as IPF and asthma. Several reports support this speculation that the female gender may represent a risk factor for development of
Figure 8. Effects of estradiol on fibrotic lung fibroblasts in vitro. Rat lung fibroblasts from BLM-treated (BRLF) and normal (NRLF) rats were isolated and treated with various concentrations of estradiol. The cells were harvested for analysis of procollagen α1(1) (A), TGF-β1 (B), IL-4 (C), and MCP-1 (D) mRNAs by RT-PCR.

The expression of MCP-1 was not significantly affected by estradiol treatment. Collagen type I and TGF-β1 expression was also assessed by immunohistochemistry and expressed as a percentage of total cells positively stained by the respective anti-collagen (E) or TGF-β1 (F) antibodies.
more severe respiratory or other fibrotic diseases. For example, there is a clear-cut gender-based difference in the prevalence and natural history of asthma, a fibrotic disease of the airways. Previous studies show that girls with asthma have poorer lung function, relapse more frequently after emergency room visits, and have a poorer prognosis than boys. Recent studies also indicate that the hospital admission rate is consistently higher among women 25 to 55 years of age and that cough sensitivity is also heightened in females. A study of 13,651 asthmatic patients showed that the disease pattern was related to sex and age. Males dominate the incidence of asthma until age 14, but from 14 to 17 years of age, the pattern changes such that by age 17 females outnumber the male incidence. At age 50, the gap begins to narrow, such that at age 60 gender-based differences are few, probably because of the reduced sex hormone production after menopause. This observation suggests that hormones may influence asthma, and thus may affect disease outcome. The proposal that asthmatic airway wall thickening may be a fibrotic response also supports the notion that gender may play a role in lung fibrosis. In agreement with these results, recent studies have further documented that the incidence of focal sclerosing glomerulonephritis is higher in women than men. In contrast another study shows that men with IPF have a decreased survival rate than women. However, this study was based on survival analysis of patients with this disease, without controlling for factors such as the stage or severity of disease, occupation, age (with respect to menopause), or average life expectancy differences among men and women. Only 38% of the study population is female, and the average age was 64 years (postmenopausal age). Because the study population contains postmenopausal patients, the potential role of sex hormones, especially estrogen, cannot be evaluated. There could potentially be confounding factors related to the use of hormone replacement therapy, but that is not addressed in these studies as well. Similarly while a study using a different model of PF in hamsters found enhanced susceptibility to fibrosis in females, another revealed no major gender-related differences in the bronchiolar epithelia metaplasia in rats in response to chronic inhalation of ozone.

With regard to the influence of ovarian hormones on disease progression, several reports support the claim that female reproductive hormones are involved in altered immune response leading to diseases such as systemic lupus erythematosus (SLE) and primary pulmonary hypertension. SLE, which primarily affects young women, involves the respiratory system more commonly than does any other collagen vascular disease and it may affect virtually all components of the respiratory system, including the upper airway, lung parenchyma, pulmonary vasculature, pleura, and respiratory muscle. A recent study found that lupus patients with a longer duration of prednisone therapy were more likely to develop carotid arteriosclerosis. Another disease typically affecting young women, primary idiopathic pulmonary hypertension may also have an autoimmune basis that is influenced by host immunogenetics. Moreover, there is evidence to suggest that tamoxifen, a synthetic nonsteroidal antiestrogen, may be effective in the treatment of idiopathic retroperitoneal fibrosis. One may speculate from this that estrogen, which is gender-specific, may have a significant influence on fibrosis and/or the inflammation that often accompanies the fibrotic response. However, ovarian dysfunction that enhanced the formation of granuloma formation in rats has been reported. Thus reports on the role of gender on PF are few and controversial, and there are no reports on the influence of gender or sex hormone on BLM-IPF.

This study attempts to meet that need by examining for possible gender-based differences in a model of BLM-induced lung injury and fibrosis. Using adult female and male rats, the results indicated that relative to male rats, female rats had greater morbidity and mortality in their response to BLM. Additionally lungs of female rats exhibited more severe and extensive interstitial fibrosis than those of male rats according to histopathological examination. Furthermore, female lung tissue showed greater degrees of lung inflammation and fibrosis that were accompanied by a higher degree of lung collagen deposition as assessed by lung hydroxyproline content. This enhanced fibrotic response in female rats was also reflected in the higher mRNA levels for procollagens α1 (I), α1 (III), as well as by greater increases in fibrogenic cytokine expression. Taken together, these findings provide support for the conclusion that there are significant gender-dependent differences in the response to lung injury, and that the female gender may represent a risk factor for the development of more severe PF. The mechanism for this observed difference might involve genetic, immune system, or hormonal factors, or some combination of these factors. Based on the gender differences, the female sex hormone is a likely factor to influence the severity of disease and decreased survival rates. The mechanism may be related to the modulating effect of estrogen hormone on the inflammatory or immune response (eg, via activation of mononuclear phagocytes, eosinophils, and/or T lymphocytes), or more directly, on fibroblast function. Activated inflammatory cells and/or fibroblasts could then release fibrogenic cytokines (TGF-β1, TNF-α, IL-4), resulting in recruitment and activation of fibroblasts/myofibroblasts with consequent collagen deposition and development of severe and progressive fibrosis.

To evaluate this potential role of estrogen, the effects of OV with or without estradiol replacement therapy were examined using the BLM model. The results revealed that OV caused a significant reduction in the response to BLM, in terms of morbidity, mortality, lung cytokine expression, and fibrosis. This reduction in responsiveness to BLM could be reversed by estradiol replacement therapy, thus suggesting that female rats were more responsive to BLM than males, primarily because of the higher level of estrogen production by the former. Moreover there was some correlation between the plasma estradiol levels and the degree of fibrosis. Interestingly, the effect of estradiol is to promote monocyte/macrophage and eosinophil influx, while suppressing T-cell influx. These effects on the inflammatory/immune response were re-
lected as well in the expression of certain cytokines. Thus OV blunted the BLM-induced lung IL-4 and TGF-β expression while suppressing IFN-γ expression. These were all reversed by estradiol replacement therapy. The suppressive effect of estradiol on IFN-γ expression is consistent with the anti-fibrotic activity of this cytokine.45–49 Thus decreased IFN-γ expression by estradiol is expected to enhance fibrosis, which was observed in these series of experiments. Taken together these findings suggest that the female gender via estrogen was able to enhance PF, at least in part by altering the inflammatory/immune responses, perhaps by modulating cytokine expression.

Finally, possibly effects of estrogen on fibroblast function were evaluated to see if an additional mechanism may be mediated directly in this manner. Fibroblasts from BLM-treated rats exhibited an altered phenotype as manifested by increased responsiveness to estradiol treatment, causing dose-dependent increases in procollagen I, IL-4, and TGF-β mRNA expression relative to untreated controls. Interestingly and consistent with the in vivo data estradiol did not significantly affect MCP-1 expression in these cells, indicating that the effect of estradiol is selective. These in vitro findings suggest an additional mechanism as to how female sex hormones may represent a risk factor for development of more severe lung fibrosis. Further studies may enable the development of new therapeutic modalities for female patients.

Acknowledgments
We thank Dr. Stephen J. Weiss for critical review of the manuscript; and Bridget McGarry, Matthew Ullenbruch, Lisa K. Riggs, and Elizabeth A. Horn for excellent technical assistance.
