The present study was undertaken to analyze the effect of a P450 aromatase inhibitor (finrozole) on 4-month-old transgenic mice expressing human P450 aromatase (P450arom) under the human ubiquitin C promoter (AROM+). AROM+ mice present several dysfunctions, such as adrenal and pituitary hyperplasia, cryptorchidism, Leydig cell hypertrophy and hyperplasia, and gynecomastia. The present study demonstrates that these abnormalities were efficiently treated by administration of a P450arom inhibitor, finrozole. The treatment normalized the reduced intratesticular and serum testosterone levels, while those of estradiol were decreased. The body weight and several affected organ weights were normalized with the treatment. Histological analysis revealed that both the pituitary and adrenal hyperplasia were diminished. Furthermore, the cryptorchid testes present in the untreated AROM+ males descended to scrotum, 4 to 15 days after inhibitor treatment. In addition, the disrupted spermatogenesis was recovered and qualitatively complete spermatogenesis appeared with the inhibitor treatment. This was associated with normalized structure of the interstitial tissue, as analyzed by immunohistochemical staining for Leydig cells and macrophages. One of the features was that the Leydig cell hypertrophy was markedly diminished in the treated mice. AROM+ mice also present with severe gynecomastia, while the development and differentiation of the mammary gland in AROM+ males was markedly diminished with the inhibitor treatment. Interestingly, the mammary gland involution was associated with the induction of androgen receptor in the epithelial cells, while estrogen receptors were still detectable in the epithelium. The data show that AROM+ mouse model is a novel tool to further analyze the use of P450arom inhibitors in the treatment of the dysfunctions in males associated with misbalanced estrogen to androgen ratio, such as pituitary adenoma, testicular dysfunction, and gynecomastia. (Am J Pathol 2004, 164:1039–1048)

Aromatase P450 (P450arom) enzyme is the product of the Cyp19 gene. The enzyme catalyzes aromatization of the A-ring of androgens such as testosterone (T) and androstenedione, resulting in formation of the phenolic A-ring characteristic of the estrogens, estradiol (E2), and estrone, respectively. Together with 17β-hydroxysteroid dehydrogenase type 1 (17β-HSD type 1), P450arom catalyzes the final steps in ovarian E2 biosynthesis, but the enzyme is also widely expressed in female and male extragonadal tissues, suggesting a role for the enzyme in the local, intracrine, estrogen production. However, the extragonadal tissues lack the capacity to synthesize androgenic precursors, and estrogen production is dependent on the precursors produced in the classical steroidogenic organs; ie, the gonads and the adrenal glands.

Aberrant estrogenic stimulation has been shown to be involved in several clinical manifestations in both sexes. Most important is the tight connection between estrogens and neoplastic transformation of breast and endometrial epithelium. Other clinical manifestations related to estrogens include gynecomastia, delayed puberty, ovulatory dysfunctions, and endometriosis. Also, several studies on mice indicate that prenatal or early postnatal exposure to exogenous estrogens induces severe and persistent changes in the structure and function of the male reproductive organs, such as atrophic and small testes, epididymal cysts, abnormalities in the rete testis, and underdevelopment of the accessory sex glands. Estrogens may also have a pivotal role in the mechanisms leading to male reproductive tract malformations such as cryptorchidism, enlarged prostatic utricle, and testicular and prostatic tumors.

Because unopposed estrogen action may lead to a number of severe health problems, the development of efficient therapies to block or reduce estrogen action is of key importance. Two different approaches are available: to reduce the systemic or local estrogen levels in the

target tissues by P450arom inhibitors, or to block estrogen action at the receptor level with antiestrogens. Both strategies have been pursued for several decades, and new molecules are continuously under development. The existence of two distinct estrogen receptors (ERα and ERβ) has made the development of pure antiestrogens a complex issue. However, this together with the new knowledge on estrogen-dependent gene activation has raised the possibility to further develop tissue-specific antiestrogens and selective estrogen receptor modulators. So far, in the human, only one gene for P450arom has been identified, indicating that full inhibition of the enzyme would result in total blockage of estrogen production from androgenic precursors, both in men and women. Hence, P450arom is a good target for inhibiting estrogen-dependent processes, without affecting the production of other steroid hormones. Recent studies have documented the clinical efficacy of P450arom inhibitors in the treatment of breast cancer and endometriosis. In addition, P450arom inhibitors have been used to treat boys with delayed puberty, to improve the expected height. Furthermore, ongoing studies address the possibility of using P450arom inhibitors in the treatment of gynecomastia and premature puberty.

We have recently generated a transgenic mouse model expressing human P450arom under the human ubiquitin C promoter (AROM+). These mice present a multitude of severe structural and functional alterations in the male reproductive tract, such as cryptorchidism, Leydig cell hypertrophy and hyperplasia, and disrupted spermatogenesis. Furthermore, the mammary glands of the AROM+ males undergo ductal and alveolar development resembling morphologically that of terminally differentiated female mammary glands, including the expression of mRNA for the milk protein β-casein. In addition to the reproductive defects, the AROM+ male mice present with enlarged size of adrenals and pituitary, and reduced body weight at young adult age. The present study was undertaken to analyze the effect of a P450arom inhibitor, finrozole, on the male AROM+ phenotype. Interestingly, the study showed that the severe phenotype in AROM+ males could be largely normalized by the inhibitor treatment. Thus, AROM+ mouse model is a novel tool for evaluating the use of P450arom inhibitors in males in vivo.

Materials and Methods

Transgenic Mouse Line Expressing Human P450 Aromatase (AROM+)

The generation of the transgenic mice expressing human P450arom cDNA under the control of the ubiquitin C promoter (AROM+) has been described previously. The AROM+ female mice were maintained in a standard colony and used as breeders, and genotyping of the AROM+ mice was carried out as described previously. The mice had free access to soy-free food pellets (SDS; Witham, Essex, England) and tap water. All mice were handled in accordance with the institutional animal care policies of the University of Turku (Turku, Finland).

Investigational Drug and Control Substances

Four-month-old wild-type (WT) and AROM+ males were divided into two groups: one group served as control group (placebo), the other group received the inhibitor (n = 10). The vehicle was prepared as follows: 0.25 g carboxymethylcellulose (Tamro Ltd., Vantaa, Finland) was weighed and solubilized in 50 ml of deionized water. The solution was prepared once per week and stored at 4°C. An appropriate amount of a P450arom inhibitor, finrozole, MPV-2213ad, (Hormos Medical Ltd., Turku, Finland) was weighed in a transparent glass mortar. A few drops of the vehicle were added, and the mixture was thoroughly mixed. Thereafter, one-third of the final volume of the vehicle was added to the mortar and placed into an ultrasonic incubator for 5 minutes. This procedure was completed a total of three times to reach the final volume. The dose of finrozole was 10 mg/kg of body weight, and it was given daily to mice by gavage in 0.2 ml for 6 weeks.

Morphological and Histological Assessment of Organs

After a 6-week-long finrozole treatment, body weight was recorded and compared to the weight measured before the treatment. The testis descending was tested as follows: abdomen of each mouse was pressed continuously with two fingers. To press the testis from abdomen to scrotum, the fingers were slid in caudal direction. If the testes were not able to descend to scrotum, the mouse was considered as cryptorchid. After the inhibitor treatment, the mice were anesthetized with 300–500 μl of 2.5% avertin, and blood was collected by a cardiac puncture. The organs were rapidly excised and weighed. Thereafter, samples were collected by freezing in liquid nitrogen or by fixing with 4% paraformaldehyde, and fixed tissues were embedded in paraffin. For histological and immunohistochemical analysis 4-μm-thick sections were deparaffinized in xylene and ethanol, and then stained with hematoxylin and eosin.

Hormone Measurements

Serum samples were separated by centrifugation and stored at −20°C until hormone concentrations were measured. Serum levels of T, luteinizing hormone (LH) were measured as previously described. For measuring the intratesticular E2 and T, testis (half testis) was homogenized in 0.5 ml PBS. Thereafter, the E2 and T were extracted from the homogenate using diethyl ether. After extraction, the organic phase was evaporated into dryness, the steroids were solubilized in an aliquot of PBS, and measured by radioimmunoassay following the manufacturer’s protocols for serum samples (Wallac Oy, Turku, Finland). The sensitivity of estradiol is 0.05 nmol/
ml. T was performed by radioimmunoassay after diethyl ether extraction, as described previously.28

Immunohistochemistry

Four-micrometer-thick sections were cut from paraffin-embedded tissues and mounted on slides. After deparaffinization and rehydration in xylene and ethanol, they were placed in 10 mmol/L citrate buffer (pH6.0), followed by heating in a microwave oven for antigen retrieval. For this, three periods of 5 minutes each were used, after which the sections were treated with 3% H₂O₂ in PBS (pH 7.6) for 20 minutes. The sections were then incubated overnight at 4°C in PBS containing 3% BSA and one of the following antibodies: 1) antibody against 3βHSD1 (rabbit polyclonal IgG) used at a 1:1000 dilution (provided by Anita H. Payne, Stanford University School of Medicine, CA), 2) antibody against estrogen receptor α (rabbit polyclonal IgG; Santa Cruz Biotechnology, Inc., Santa Cruz, CA) used at a 1:200 dilution, 3) antibody against ERβ (chicken polyclonal IgG; provided by J. Å. Gustafsson, Department of Medical Nutrition, Karolinska Institute, Stockholm, Sweden) used at a 1:1000 dilution, 4) antibody against activated signal transducer and activator of transcription 5 (Stat 5; mouse monoclonal IgG; Upstate Biotechnology, Lake Placid, NY) used at a 1:500 dilution, 5) antibody against Prl (rabbit polyclonal anti-serum; National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD) used at a 1:500 dilution, 6) antibody against F4/80 macrophage marker (rat polyclonal IgG2b, Serotec Ltd. Oxford, UK) used at a 1:50 dilution, 7) antibody against androgen receptor (rabbit polyclonal IgG; Santa Cruz Biotechnology) used at a 1:500 dilution, and 8) antibody against PCNA (mouse monoclonal IgG, NovoCastra, Newcastle, UK) used at 1:200 dilution.

The primary antibody bound was detected by using biotinylated goat anti-rabbit IgG, rabbit anti-mouse IgG or mouse anti-rat IgG (1:200 dilution) followed by incubation with avidin-biotin-peroxidase complex (Vector Laboratories, Burlingame, CA). The sections with ER antibodies were incubated with peroxidase-conjugated rabbit anti-chicken IgG (1:1000 dilution). The specific binding was visualized by using 3’–3’ dianinobenzidine tetrahydrochloride. Sections were slightly counterstained with Mayer’s hematoxylin and mounted.

Statistics

SigmaStat software (SigmaStat 2.03 for Windows; SPSS Inc., Chicago, IL) was used for one-way analysis of variance and differences between individual means were assessed by all-pairwise multiple comparison procedures (Student-Newman-Keuls test for T, E2, and LH, and Duncan’s tests for testis, adrenal, and pituitary gland).

Results

In the recent study we evaluated the response of 4-month-old male mice expressing P450 arom on a P450 arom inhibitor. The data show a strong treatment response in the weight of various affected organs. The changes were further analyzed in cellular level by performing histological analyses of the affected organs, while immunohistochemical analyses and hormonal measurements were used to define signaling systems involved.

Hormone Concentrations in AROM+ Males after Finrozole Treatment

To analyze the consequences of the P450 arom inhibitor on testicular steroid production, intratesticular T and E2 concentrations were measured in inhibitor-treated AROM+ males, and compared with the placebo-treated AROM+ and non-treated and treated WT males. Furthermore, serum levels of T and LH were measured. Significantly increased intratesticular E2 concentration (P < 0.001) was found in AROM+ males in connection with a decreased T (P > 0.001; Figure 1). The low level of testicular T was reflected to a markedly lowered level of circulating T, as also reported previously.28 As expected, the elevated intratesticular E2 present in AROM+ was significantly reduced by the finrozole treatment (Figure 1), although it still remained four-fold higher as compared to the level found in placebo-treated WT mice. In contrast to the reduced E2, intratesticular T concentration was increased in the AROM+ males after inhibitor treatment, reaching the level found in WT mice (P = 0.6; Figure 1). In line with our previous results no significant difference was found in the serum LH concentrations (Figure 1).

Body and Organ Weights, and Histology of Non-Reproductive Tissues Are Restored by Finrozole Treatment

The comparison of organ weights in placebo and finrozole-treated WT and AROM+ male mice are presented in Table 1. All abnormalities in organ weights induced by the increased E2 to T ratio were found to be either partially or totally reversible. In AROM+ mice the lowered body weights were normalized by the finrozole treatment, in line with the anabolic effect of the increased circulating T concentration. The increased serum T concentration in the treated AROM+ mice is in line with the significantly
increased testis and seminal vesicle weight in these males (Table 1).

AROM+ males were previously shown to have increased pituitary size and highly elevated concentrations of serum Prl.25 The inhibitor treatment resulted in a marked inhibition of the growth of the pituitary in AROM+ males (Table 1), and immunohistochemistry revealed that the amount of prolactin production in the pituitary was strikingly decreased in inhibitor-treated AROM+ males as compared with placebo-treated AROM+ males (Figure 2, A–E).

In agreement with our previous study, the weights of the adrenal glands in the placebo-treated AROM+ mice were more than three-fold higher than those in the WT mice. Inhibitor treatment reduced the growth of the adrenals in AROM+ mice, resulting to a 50% smaller adrenal

Statistical analyses were carried out to compare all the groups together, but significance is shown only for the data between AROM+-placebo and AROM+-inhibitor groups. Asterisks indicate a significant difference (*, P < 0.01).

Figure 2. A–E: Localization of Prl-producing cells in the pituitary gland. Pituitary sections from WT mice (A and B), AROM+-placebo (C and D), and finrozole-treated AROM+ (E) male mice were stained with an antibody to rat Prl. Higher magnifications (B and D) indicate specific brown staining in the cytoplasm (arrows). F–K: Histology of the adrenal gland in WT (F and I), AROM+-placebo (G and J), and finrozole-treated AROM+ (H and K) male mice. In AROM+-placebo mice, large vacuole-filled cells appeared in the innermost cortex (J, arrow). The thickness of the cell layer was reduced after finrozole treatment (H and K). Scale bars: 50 μm (A, C, E), 100 μm (F–K).
size in the inhibitor-treated AROM+ males as compared with the placebo-treated AROM+ males (Table 1; Figure 2, F–H). Histological analysis furthermore showed that the number of large vacuole-filled cells in the innermost AROM+ adrenal cortex was reduced by the finrozole treatment (Figure 2, F–K).

Reversal of Testicular Structure and Function by Finrozole Treatment in AROM+ Males

One of the interesting features of the inhibitor treatment was that the cryptorchid testes of the AROM+ males descended into scrotum with 100% penetrance, 4 to 15 days (median 12 days) after starting the finrozole treatment (Figure 3A). This was associated with a recovery of the androgen production and testicular function. The intraabdominal descent of the testes was normal in AROM+ mice, as indicated by the fact that that in newborn mice the testes were located at the bladder neck (Figure 3, B and C). Furthermore the intratesticular T concentration in embryonic day 17.5 is identical in WT and AROM+ males.

**Histological examination of the finrozole-treated testes also revealed that the relative volume of testicular interstitial space/tubular volume reduced toward that found in WT mice. Evidently, the interstitial space in the AROM+ testes were filled with hypertrophic Leydig cells, as confirmed by immunohistochemical staining with markers, such as P450 side-chain cleavage (not shown) and 3β-hydroxysteroid dehydrogenase type I (Figure 4, E–G), while in the inhibitor-treated mice the Leydig cells clusters were smaller and triangular in shape. Furthermore, the macrophages present in the testis in AROM+ mice were increased in size (Figure 4, H–K), thereby together with the Leydig cells, they fill up the relatively large intestinal space in the placebo-treated AROM+ mice (Figure 4). Histological analysis revealed that the size of the interstitial macrophage population was normalized in the inhibitor-treated mice; however, after inhibitor treatment some large macrophages still remained in the interstitium. Furthermore, after the inhibitor treatment the seminal vesicle weights did not reach the normal size, and the hypertrophic Leydig cell still sustained in some parts of interstitial region, suggesting that the dose of finrozole (~240 μg/kg/day) was not high enough to completely normalize the testicular endocrine functions.

**Inhibitor Treatment Induces Mammary Gland Involution in AROM+ Male Mice

AROM+ males show severe gynecomastia, with highly differentiated mammary glands (Figure 5). Interestingly, as previously reported, the P450arom inhibitor treatment markedly blocked the development and differentiation of the mammary gland, as shown by a whole-mount staining of the mammary gland (Figure 5A). To further study the mechanisms of the inhibitor-induced changes, certain signaling pathways were analyzed in the AROM+ mice with and without finrozole treatment. The data revealed the presence of both ERα and ERβ in the ductal or alveolar epithelium (Figure 5, B and C). To determine whether the involution of mammary gland could, at least partly, be a result of the elevated circulating T, we examined androgen receptor (AR) expression by immunohistochemistry. Surprisingly, AR was strongly expressed in the alveolar epithelium of finrozole-treated AROM+ mice, but absent in the other groups analyzed (Figure 5D). The decreased secretion of prolactin from the pituitary was in line with a reduced staining of the mammary epithelium with phosphorylated Stat5 antibody (Figure 5E).

**Discussion

The male AROM+ mice are novel tools for analyzing the effects of chronic exposure of males with elevated circulating E2, combined with a slightly reduced T concentration. The misbalanced sex-steroid action results in development of abnormalities in various organs, especially in the reproductive tract, and the mice are infertile. The transgene is expressed in various extragonadal tissues of the AROM+ mice, thereby also providing a local E2 producing machinery. AROM+ males display changes similar to those observed in male rodents exposed perinatally to estrogens, such as undescended testes, testicular interstitial cell hyperplasia, and hypoandro-
genism with growth inhibition of the accessory sex
glands. The recently documented reduction in reproduc-
tive health in men has been proposed also to be related
to exposure to endocrine-disrupting chemicals with es-
trogenic action.29 However, the role of estrogens in this
phenomenon is still under debate. The incidence of tes-
ticular cancer,30,31 hypospadias, and cryptorchidism ap-
pear to be increasing,32,33 and estrogens have been
suggested to be involved in the development of the dis-
orders, also referred to as testicular dysgenesis syn-
drome (TDS),34 or developmental estrogenization syn-
drome.35

A growing number of studies have reviewed the ex-
pression of P450arom and ERs in male reproductive sys-
tem.36,37 It is evident that estrogen action is needed for
normal reproductive physiology in male.19,36 ERα knock-
out mice show dilated lumen of the testicular seminifer-
ous tubules, and disrupted epididymal function.38 Simi-
larly, mice deficient in P450arom are infertile at old age.39
In addition, it has been reported that a chronic adminis-
Aromatase Inhibitor on AROM+ Male Mice

Artemio Abreu and Kerry S. Lim

Inhibition of a P450arom inhibitor, anastrozole, results in a significant increase in testis weight and circulating and intratesticular T concentration in rats. Furthermore, a recent study suggested that administration of E2 within a dose typically found in females can induce the spermatogenesis in hpg male mice, and despite of the increase in testicular weight, circulating androgen concentrations were still undetectable. However, the amount of E2...
supporting normal testis function forms a narrow window, while animal models with mild overexpression of P450arom show testicular interstitial cell abnormalities and disrupted spermatogenesis.25,42 There is clear evidence that LH plays a pivotal role in development of the Leydig cell population and stimulating T production in adults.43,44 In addition, LH is believed to be the main trophic hormone that causes Leydig cell adenomas,43 while there is evidence showing that estrogens induce Leydig cell adenomas via their ability to increase LH action in certain strains of mice.45,46 However, our recent study showed that mice with a marked overexpression of hCG do not develop Leydig cell hyperplasia in adulthood.47 These data speak against a major role of LH as a growth stimulator in estrogen-exposed mouse testes. Furthermore, in an AROM+/+ mouse model the LH level is in normal range. The effects in AROM+ males are largely recovered by finrozole as indicated by normalized Leydig cell structure and function, and by the qualitatively full spermatogenesis, further suggesting that estrogen action in the testis is the primary cause of the testicular abnormalities in AROM+ mice. Hence, more studies are emerging to analyze the direct effects of estrogens in the testis, and whether P450arom inhibitors could be beneficial in the treatment of human Leydig cell tumors remains to be studied.

AROM+ mice showed fully descended testes after finrozole treatment, and also after testicular androgen production was normalized. This gives rise to a hypothesis that P450arom inhibitors could be used to treat cryptorchidism in humans. The exact mechanisms of cryptorchidism that P450arom inhibitors could be used to treat cryp-

production was normalized. This gives rise to a hypoth-

AROM+ mice showed fully descended testes after finrozole treatment, and also after testicular androgen production was normalized. This gives rise to a hypothesis that P450arom inhibitors could be used to treat cryptorchidism in humans. The exact mechanisms of cryptorchidism in boys are still largely unknown, but abnormal estrogen action has been suggested as one of the possible causes.48 Fetal exposure to high concentrations of estrogens causes cryptorchidism in rodents.13,49,50 The estrogen-induced cryptorchidism is associated with down-regulating the InsL3 gene expression,50 a hormone involved in gubernaculums development responsible for trans-abdominal testis descent.51,52 However, no conclusive evidence exists for the role of InsL3 in human cryptorchidism.53,54 Our present data suggest that the InsL3-dependent intra-abdominal descent had occurred normally in AROM+ males. Hence, it is likely that the lack of improper postnatal and pubertal androgen production is the main cause to their cryptorchidism. Interestingly, correcting the androgen/estrogen balance at adult age by a P450arom inhibitor treatment (present study) restored normal inguinal descent of the testes in the AROM+ mice.

Gynecomastia is a clinical manifestation that is related to estrogen action in the males, and ongoing studies have addressed the possibility of using P450arom inhibitors in the treatment of gynecomastia.7,24 Interestingly, AROM+ males display mammary gland development with several features identical to gynecomastia in men. Both the ERα and ERβ were expressed in AROM+ male mammary glands, and the signal transduction pathways via PrIR were activated, as shown by the presence of phosphorylated Stat5 proteins.26 This is in line with results showing the presence of ERs and progestin receptor (PR), as well as PrIR in the mammary gland of men with gynecomastia.55–57 The development of gynecomastia in AROM+ males was efficiently treated with a 6-week inhibitor treatment, as demonstrated by whole-mount staining of the mammary glands. Interestingly, the inhibitor treatment did not eliminate ERα expression, while ERβ protein was less stainable after inhibitor treatment. In the male fetus, T produced by the testis is known to be involved in regression of the mammary bud in the male, starting on gestation day 13 in mice.58 In the absence of this T-induced regression, the mammary gland maintains its full competence for development in male mice.59,60 The demonstration of AR in the inhibitor-treated AROM+ mammary epithelium with increased circulating T suggests an antiproliferative function for androgens also in the adult male mammary epithelium. Clinical data also suggest that androgens suppress mammary growth in men.61 It has also been shown that while E2 stimulates the proliferation of mammary epithelial cells in a primate model, its proliferative effect is significantly reduced by T.62 Clinically, androgens have been used in the past for the treatment of breast cancer with some success.63 The possibility that the AR signaling pathway is active in the male mammary gland is also supported by the results showing that gynecomastia often develops as a consequence of antiandrogen therapy, and high doses of aromatizable androgens.63

The development of pituitary lactotroph adenomas is a typical response in rodents exposed to increased level of estrogens.64,65 Interestingly, the present data suggest that the pituitary in males is more sensitive to the estrogen exposure than that in females. AROM+ males have relatively low circulating levels of estrogens that do not exceed the normal level in females, yet they develop severe lactotroph adenomas, and the adenoma development is efficiently inhibited by P450arom inhibitor. Another interesting linkage exists between the enhanced estrogen action and the enlargement of the adrenal in AROM+ mice. AROM+ mice show the estrogen-dependent hyperplastic cells in the adrenal cortex, while the mechanisms of the hyperplasia remains to be studied.

In conclusion, the present data show that P50arom inhibitor treatment reduces the E2/T ratio, and the severe phenotype in AROM+ males could be largely normalized. These observations indicate that the AROM+ mouse model is a novel tool for evaluating the effects of compounds that interfere with estrogen production or action in males in vivo.
