Vinculin and its muscle splice variant metavinculin link focal adhesions and cell-to-cell contact sites to the actin cytoskeleton. We hypothesized that normal expression of vinculin isoforms would be essential for integrity of cardiomyocytes and preservation of normal cardiac function. We studied heterozygous vinculin knockout mice (Vin+/−) that develop and breed normally. The Vin+/− mice displayed: 1) a 58% reduction of vinculin and a 63% reduction of metavinculin protein levels versus wild-type littermates; 2) normal basal cardiac function and histology but abnormal electrocardiograms, intercalated disks, and ICD-related protein distribution; 3) increased mortality following acute hemodynamic stress imposed by transverse aortic constriction (TAC); 4) cardiac dysfunction by 6 weeks post-TAC; and 5) misalignment of α-actinin containing Z-lines and abnormal myocardial ultrastructure despite preserved cardiac function. These results indicate that reduced expression of vinculin/metavinculin leads to abnormal myocyte structure without baseline physiological evidence of cardiac dysfunction. These structural changes predispose to stress-induced cardiomyopathy.

Vinculin (Vin) is a 117-kd ubiquitously expressed, membrane-associated protein that links focal adhesions (cell-substrate contacts), adherens junctions (cell-to-cell contacts), and costameres (subsarcolemmal adhesion plaques) to the actin cytoskeleton. In cardiac myocytes, vinculin is detected at the lateral sarcolemma, in transverse ribs called costameres, in Z-lines, as well as at cellular attachment sites termed intercalated disks (ICDs).

Dilated cardiomyopathy has been associated with mutations in a number of structural proteins, and many such studies have shown that the link from sarcomere to cell membrane is critical for preservation of normal myocardial function and integrity. Relevant to the focus of the current examination is that a 124-kd splice-variant isoform of vinculin, termed metavinculin (Mvin), is expressed only in cardiac and smooth muscle. Alterations in metavinculin have been recently related to human cardiomyopathy.

Homozygous inactivation of the murine vinculin gene caused embryonic lethality by E10.5. The embryos displayed a thin-walled myocardium and cerebral abnormalities including incomplete fusion of the neural folds. The heterozygous knockout mice (Vin+/−) develop and breed normally and are the focus of the current study. We hypothesized that reduced expression of vinculin/metavinculin in the intact Vin+/− mouse heart would lead to impaired cardiac function either in the basal condition or following hemodynamic stress. The strategy used to inactivate the vinculin gene in these mice leads to impaired production of vinculin as well as metavinculin. We found that the Vin+/− mice displayed: 1) a 58% reduction of vinculin and a 63% reduction of metavinculin protein levels versus wild-type littermates; 2) normal basal cardiac function and histology but abnormal electrocardiograms, intercalated disks, and ICD-related protein distribution; 3) increased mortality following acute hemodynamic stress imposed by transverse aortic constriction (TAC); 4) cardiac dysfunction by 6 weeks post-TAC; and 5) misalignment of α-actinin containing Z-lines and abnormal myocardial ultrastructure despite preserved cardiac function. These results indicate that reduced ex-
pression of vinculin/metavinculin in the mammalian myocardium alters myocyte structure and can predispose to stress-induced cardiac dysfunction.

**Materials and Methods**

**Antibodies and Fluorochromes**

The following antibodies were used: mouse monoclonal anti-pan-vinculin (which can detect both vinculin and metavinculin forms) (clone hVIN-1, Sigma, V9131); mouse monoclonal anti-sarcomeric-α-actinin (clone EA-53, Sigma, A7811); rabbit polyclonal anti-pan-cadherin (Sigma, C3678); rabbit polyclonal anti-connexin 43 (CX43) (Sigma, C6219); rabbit polyclonal anti-β1D integrin; mouse monoclonal anti-pan-cadherin,15 mouse monoclonal anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (Research Diagnostics Inc., TRK5G4–6C5); horseradish peroxidase (HRP) conjugated anti-mouse/anti-rabbit (Jackson ImmunoResearch; 115–175-4677–035-152), rhodamine-labeled phalloidin (Molecular Probes, R-415); Alexa Fluor 488 goat anti-mouse/anti-rabbit (Molecular Probes, A-11029/A-11034); and 4',6-diamidino-2-phenylindole dihydrochloride (DAPI) (Sigma, D-9542).

**Vinculin Knockout Mice**

The strategy used to produce these mice was previously described.14 Briefly, exon 3 was deleted, which prevents production of both vinculin and metavinculin protein from the targeted allele. Genotypes of all mice were determined by polymerase chain reaction with primers P1, P2, P3, and P4. The sequences of these primers were: P1 (exon 3 823 forward) 5'-CGG CGG GAT TAC CTC ATT GAC-3'; P2 (exon 4 1642 reverse) 5'-TGG TCA CCT GGC CCA AGA TTC TTT-3'; P3 (neomycin 479 forward) 5'-CCG GCC ACA GTC GAT GAA TC-3'; and P4 (neomycin 933 reverse) 5'-TGC TCA CCT GGC CCA AGA TTC TTT-3'. PCR with these primer sets resulted in a 474-bp neomycin product and an 843-bp exon 3/4 product from the WT allele. All mice were housed in an Association for the Assessment and Accreditation of Laboratory Animal Care (AALAC) approved facility.

**Western Blotting**

Freshly isolated hearts were washed in ice-cold PBS, immediately frozen in liquid nitrogen, pulverized, homogenized in modified RIPA buffer, and analyzed via techniques as described previously.16,17 Whole heart protein lysate was resolved by SDS-PAGE and Western blots were performed to detect vinculin/metavinculin and GAPDH. Blots were incubated with primary antibodies overnight at 4°C. Dilutions were anti-vinculin (1:5000) and anti-GAPDH (1:5000–1:30,000). Densitometric quantitation of protein bands was performed digitally with Alphagene software (Chemilagram 4400, a Innotech Corp., San Leandro, CA). All sample intensities were normalized to the GAPDH signal as a loading control.

**Tissue Acquisition, Morphometry, Histology, Electron Microscopy, and Processing for Immunofluorescence Microscopy**

For morphometric analyses, the animals were sacrificed at 3, 4, and 6 months of age. Postoperatively, one group of animals was sacrificed after 4 weeks and a second group after 12 weeks. At sacrifice, hearts were arrested in diastole by injection of a high potassium solution (25 mmol/L KCl and 5% dextrose in 1X PBS). Heart tissue was preserved for histology or immunohistochemistry as previously described.17 For electron microscopy (EM) studies, three samples from each genotype were analyzed. Samples were obtained from basal mice at 4 months of age. They were fixed in Karnovsky's fixative (4% paraformaldehyde, 2.5% glutaraldehyde, 5 mmol/L CaCl2 in 0.1 mol/L Na cacodylate buffer, pH 7.4) overnight at 4°C followed by 1% OsO4 in 0.1 mol/L Na cacodylate buffer, pH 7.4, for 1 hour at room temperature. Tissue pieces were then en bloc stained with 4% uranyl acetate in 50% ethanol and subsequently dehydrated using a graded series of ethanol solutions followed by propylene oxide and infiltration with epoxy resin (Scipoxy 812, Energy Beam Sciences, Agawam, MA). After polymerization at 65°C overnight, thin sections were cut and stained with uranyl acetate (4% uranyl acetate in 50% ethanol) followed by bismuth subnitrate. Sections were examined at an accelerating voltage of 60 kV using a Zeiss EM10C electron microscope.

For immunohistochemistry, 10-μm cryosections were prepared via standard technique and stained with antibodies as outlined.16 Antibodies were diluted as follows: anti-vinculin (1:700), anti-α-actinin (1:500), anti-pan-cadherin (1:600), anti-connexin-43 (1:600), phalloidin (1:300), DAPI (1:1000) and all secondary antibodies (1:200). Control sections stained with the primary antibodies alone did not detect autofluorescence of the heart tissue and no significant background fluorescence was evident in the sections stained with secondary antibody alone. The results were visualized via standard immunofluorescence microscopy (Zeiss), confocal (Leica TSC-SP or Zeiss LSM 5 PASCAL microscopes) or deconvolution (Deltavision, Applied Precision, Inc., Seattle, WA) imaging.

**Intercalated Disk Scoring**

Cryosections from five wild-type and five Vin+/− hearts were analyzed. Specimens were stained with the indicated antibodies and areas with longitudinally oriented myocytes were located in each of the hearts. Five areas from each heart (25 fields per genotype) were analyzed via confocal or deconvolution microscopy (as above) in a manner similar to that described previously.18 Analysis of the digitized images was performed by two observers who were blinded to the genotype of the specimens. ICDs per field were counted and judged by their staining pattern as either normal or wide and disrupted. The percentage of normal ICDs was calculated for each genotype. The interobserver variability was not statistically significant.
Physiological, Surgical, and Echocardiographic Procedures

Wild-type and heterozygote vinculin KO mice were anesthetized with Avertin (2,2,2, tribromoethanol, 2.5% solution, 0.016 ml/g body mass, Aldrich Chemical Corp.) or isoflurane. Echocardiography (M-mode, 2-D and Dopper) was performed and then measured by investigators blinded to the genotype of the animal, as previously described.17,19

Mouse electrocardiograms (ECGs) were obtained in anesthetized animals with subcutaneous electrodes (Grass Instruments, Warwick, RI). Recording was performed with a custom-designed ECG amplifier that was optically isolated and optically coupled. Power for the amplifier was supplied by light-emitting diode photocells to reduce electronic noise. Measurements were made according to London as outlined in Figure 3.

Transverse aortic constriction was performed on 8-week-old male mice (28–31 g) with a 26-gauge needle to induce a fixed left ventricular pressure overload, as previously described.17,21 Sham surgery, identical except for the aortic constriction, was performed in both groups. Surgeries were performed on mice of both genotypes in a mixed/random manner by a surgeon blinded to the genotype of the animal at the time of surgery. A test group of animals underwent acute aortic constriction and the systolic pressure gradient across the surgical aortic stenosis was determined by bilateral carotid catheterization. Additional groups of animals undergoing TAC or sham operations were sacrificed at 4 or 12 weeks postoperatively. Echocardiographic evaluation was performed before and at 4, 6, 8, and 12 weeks following surgery.

Invasive hemodynamic determinations were performed at baseline and following dobutamine infusions as previously described.22 The measurements were acquired, digitized, displayed, and analyzed with HEM V3.3 software (Notocord Systems, Croissy sur Seine, France). All hemodynamic data were recorded continuously for at least of 30 minutes to ensure stable levels of pressures and heart rates.

Statistical Methods

Data were compiled and are shown as means ± standard errors of the mean (SEM). Data were evaluated using unpaired, two-tailed t-tests (95% confidence interval) or two-way repeated-measures analysis of variance with post hoc analysis using a Bonferroni test and GraphPad Prism4 software (GraphPad Inc, San Diego, CA). P < 0.05 was considered significant.

Results

Cardiac Vinculin Protein Levels Are Reduced to Less than 50% of Wild-Type Levels in Vin+/- KO Mice

Whole heart lysates from Vin+/- (n = 6) and WT mice (n = 6) were used for Western blotting with an anti-

vinculin antibody. GAPDH protein expression was used as an internal loading control. Densitometric analyses showed a 58% reduction of vinculin and a 63% reduction in metavinculin protein levels, in the Vin+/- mice, compared to wild-type mice (Figure 1).

Vinculin+/- Hearts Are Histologically and Functionally Normal in the Basal State but Show Abnormal Baseline Electrocardiograms

To evaluate the consequences of reduced vinculin expression on cardiac form and function, histological and physiological assessments of the Vin+/- and control hearts were performed. Histological evaluation in the basal state showed no evidence of interstitial fibrosis, necrosis, or alterations in the myocardial architecture in mice up to 6 months of age (Figure 2, A and B). Echocardiography was performed in Vin+/- and wild-type littermate control animals up to 18 months of age to assess wall thicknesses, LV chamber dimensions and indices of cardiac function (by % fractional shortening (%FS) or velocity of circumferential fiber shortening (Vcf)). No significant differences were detected between the groups at either age. (Table 1). Invasive hemodynamics were performed at baseline and following dobutamine stimulation in 3-month-old Vin+/- and wild-type control mice via retrograde cannulation of the left ventricle using a 1.4F Millar catheter (Figure 2, C–F). No significant differences were detected in HR, pressures, or hemodynamic responses of the Vin+/- versus WT mice at baseline or after adrenergic stimulation. ECGs recorded in sedated animals showed no differences in heart rates or PR intervals, but widened QRS complexes were noted in Vin+/- animals (n = 12 each, P < 0.007; Figure 3).

Cytoskeletal Proteins and Intercalated Disks Are Abnormal in the Vinculin+/- Mice

Given the above findings in combination with the known cellular localization of vinculin, we evaluated the distribu-
tion of cytoskeletal/membrane-associated proteins in the myocardium of Vin+/− as compared to littermate control hearts. Vinculin itself was found to have abnormal morphology and distribution at the intercalated disks despite continued normal localization of the protein at the lateral cell membranes (Figure 4, A and B). Since vinculin is localized at cell-cell junctions and ECG abnormalities were detected in the Vin+/− mice, we next evaluated the expression pattern of intercalated disk proteins. We studied connexin 43(Cx43) expression since this is the pre-dominant gap-junction protein in the ventricular myocardium (Figure 4, C and D).23,24 Cadherin expression was also evaluated as representative of adherens junctions (Figure 4, E and F). Using either confocal or deconvolution microscopy, localization of both Cx43 and cadherin was found to be abnormal. The expression of both of these proteins was detected more frequently in widened ICDs in Vin+/− mice than WT (n = 5 mice of each genotype, P < 0.002; Figure 4G and Table 2).

Micrographs from five mice of each genotype were digitally acquired. The micrographs were analyzed by two observers in a genotype blinded fashion. ICDs per field were counted and ICD structure was judged by their Cx43 or pan-cadherin staining pattern as either normal or wide. Percentage of normal and wide ICDs was calculated for each genotype. Results are displayed as means ± SEM.

Cardiovascular Stresses Leads to Sudden Death and Ventricular Dysfunction in the Vinclun+/− Mouse

Since no functional changes were noted in the basal myocardium, we evaluated how Vin+/− mice would tolerate stressful stimuli. We investigated the effect of pressure overload using the well established model of transverse aortic constriction.17,21 First, acute aortic constriction was performed and showed no difference in pressure gradients between wild-type and Vin+/− groups (47 ± 7 mm Hg in WT vs. 49.8 ± 3.3 mm Hg in Vin+/−, n = 5 per group). Subsequently, 8-week-old male mice were used for a chronic TAC study. Initially we enrolled mice into a study where they were followed up to 12 weeks postoperatively and evaluated at distinct time points for cardiac function by echocardiography (Figure 5). At time of entry into the study, animal groups and numbers were: WT Sham (n = 7) Vin+/− Sham (n = 6), WT TAC (n = 9), Vin+/− TAC (n = 9). While all animals survived the surgery and were ambulatory, 33% of the Vin+/− TAC group died spontaneously during the first 3 to 6 hours following this initial postoperative recovery, leaving 6 in this group that were followed subsequently. (Identical perioperative mortality was seen in a second
Vin+/− had similar increases in ventricular posterior and septal wall thicknesses (Figure 6, C and D) when compared to their sham controls. These data are consistent with an appropriate adaptive physiological response to pressure overload. At 4 weeks after surgery no detectable difference was seen between the Vin+/− TAC or WT TAC groups; however, beginning at 6 weeks, and subsequently at 8 and 12 weeks post-TAC, LV function decreased only in Vin+/− mice (Figure 6, A and B). An increased end-systolic dimension (LVESD) was detected only in Vin+/− TAC versus other groups, consistent with their contractile failure (Figure 6F).

α-Actinin/Z-Line Registration Is Abnormal in Vinculin+/− Mice

Since the vinculin+/− mice were relatively intolerant of TAC and vinculin is localized to costameres, Z-lines and cell-cell junctions, we evaluated the cellular structure of the myocardium in unstressed Vin+/− animals as well as in those following aortic constriction. For this study we performed (as outlined above) a second TAC study and sacrificed animals at 4 weeks postoperatively when cardiac function by echocardiography was identical in WT and Vin+/− groups. The number of animals used for this study were: WT Sham (n = 9), Vin+/− Sham (n = 6), WT TAC (n = 7), Vin+/− TAC (n = 12).

We studied a representative group of proteins (vinculin, β1D integrin, and cadherin) which could be altered within the cytoskeleton, focal adhesion or intercalated disk. We also evaluated the distribution of additional proteins which bind directly to vinculin, namely sarcomeric α-actinin and talin (Figure 7). Myocardial tissue was analyzed at 4 weeks following initiation of TAC, a time period when normal cardiac function was found in Vin+/− animals and WT controls. Random fields were evaluated from specimens that showed clearly delineated longitudinal orientation of myocytes. Confocal microscopy showed that Vin+/− hearts had abnormal vinculin and cadherin staining in widened intercalated disks both at baseline and in the post-TAC specimens (Figure 7A). Z-line registration, visualized by α-actinin staining, appeared mildly abnormal in sham-operated Vin+/− animals, as compared to sham-operated littermate WT controls. Following hemodynamic stress with TAC, misalignment of Z-lines became even more evident in the Vin+/−, while WT TAC animals continued to display normal registration (Figure 7B). These results imply that normal expression of vinculin is required for maintenance of proper architecture of the cardiac myocyte.

independent TAC study used for immunomicroscopic analyses; see animal numbers below.) All sham animals of both genotypes and all WT TAC mice survived through the surgery and acute postoperative period. Only 30% of Vin+/− TAC mice survived up to the 12-week period following TAC versus 100% of the WT TAC.

Cardiac function was determined by echocardiography before surgery and at 4, 6, 8, and 12 weeks following TAC (Figure 6). At 4 weeks post-TAC, both WT mice and
Electron Microscopy of Vin+/− Hearts Shows Abnormalities of Myofibril Anchorage at the Intercalated Disks and Z-Lines as well as Mitochondrial Alterations

To further investigate the abnormalities detected in the myocytes of Vin+/− mice, we performed electron microscopy on ventricular specimens from three Vin+/− hearts and three WT hearts in their basal state. Samples were obtained from 4-month-old mice so that the WT and Vin+/− animals would both have normal cardiac function. We specifically evaluated tissue which revealed longitudinally oriented myocytes. In each of the Vin+/− samples as compared to WT sections, increased separation of myofibrils was noted as clearing adjacent to intercalated disks as well as Z-lines. In addition, mitochondria in the Vin+/− mice appeared less densely packed and with swollen cristae. Examples of representative micrographs obtained from mice of each genotype are shown in Figure 8.

Discussion

We used heterozygous vinculin knockout mice to explore the role of this protein in the myocardium. Vin+/− mice showed reduced expression of vinculin and its muscle-specific isoform metavinculin to less than 50% of wild-type levels. This resulted in several important findings. The Vin+/− mice appeared normal at baseline and were able to breed appropriately. In the basal Vin+/− mice, we found: 1) no significant changes in ventricular function as determined by invasive catheterization or echocardiography up to 18 months of age; 2) normal cardiac morphology, morphometry, and light microscopic histology; 3) that the ECG QRS duration was greater than in WT mice; 4) immunomicroscopic analyses of vinculin itself, connexin-43, and cadherin were abnormal in the intercalated disk; and 5) electron microscopy showed disturbances of the myofibril attachment at intercalated disks and Z-lines. Ultrastructural examination of mitochondria was also abnormal in the Vin+/− mice compared to WT. With acute transverse aortic constriction, substantial mortality was noted in the Vin+/− animals but not in wild-type littermate controls. With TAC, only 67% of the Vin+/− animals survived past the perioperative period. These surviving mice initially developed identical changes in left ventricular wall thicknesses and mass as compared to the wild-type controls. By 6 weeks post-TAC, the Vin+/− group showed a decline in LV function and substantial mortality resulted only in this group. Heart specimens were analyzed from animals at 4 weeks after sham surgery or TAC when normal cardiac function remained. Z-line registration was mildly abnormal only in the Vin+/− sham group but not the WT sham, as shown by immunostaining of vinculin’s direct binding partner, α-actinin. The immunomicroscopic changes became more profound in the Vin+/− mice subjected to stress (TAC), whereas no alterations occurred in the stressed WT mice. Ultrastructural analysis of Vin+/− basal, unstressed myocardium, displayed abnormal insertion of myofibrils at Z-lines and intercalated disks, as well as disturbances of mitochondria. These results suggest that normal amounts of cardiac vinculin expression are required for myofibril anchorage into the Z-line and intercalated disk as well as preservation of normal mitochondrial architecture.

As a response to mechanical stress, cardiac myocytes remodel their anchorages from the extracellular matrix through the cytoskeleton to the sarcomere. In basal, non-stressed hearts, we detected ultrastructural abnormalities in the Vin+/− hearts that were physiologically normal by several methods. Prior work using immuno-electron microscopy had established that vinculin was located immediately adjacent to the fascia adherens region of the ICD membrane. The changes in myofibrillar attachment to Z-lines and intercalated disks in the Vin+/− mice could clearly predispose them to develop cardiac dysfunction when provoked by pathological conditions such as aortic constriction. It is also interesting to note that mitochondrial abnormalities were detected in the Vin+/− specimens. Mitochondrial disturbances like these were similarly detected in mice null for the intermediate filament desmin. It is possible that this mitochondrial problem could also have contributed to the cardiac dysfunction of the Vin+/− hearts subjected to hemodynamic stress.

In TAC-stressed Vin+/− hearts that were still physiologically normal, we also detected abnormalities in Z-line structure as indicated by α-actinin immunostaining. No similar findings were seen in identically stressed WT hearts. While we cannot exclude that this Z-line abnormality is indicative of early heart dysfunction, vinculin’s direct link to α-actinin suggests that its loss from this critical mechanosensitive linkage could be a primary initiator of the myocardial decompensation cascade. These immunomicroscopic findings are in agreement with the EM ones discussed above. In this location, vinculin could be crucial for maintaining normal sarcomere stability by cross-linking α-actinin to actin. Abnormalities in several Z-line proteins including desmin, actin, and α-actinin-associated LIM protein (ALP) have been previously associated with cardiomyopathies. Not only may disturbance of the Z-line lead to structural abnormalities in the cardiac myocyte, but this region may function as a critical signaling nidus for molecules such as protein kinase N (PKN) and G protein-coupled receptor kinases (GRKs). Of particular relevance for our study is that vinculin has a splice variant isoform termed metavinculin which is expressed exclusively in cardiac and smooth muscle, and perhaps skeletal muscle. In heart, the dominant iso-
form is still the ubiquitously expressed vinculin. The heterozygous knockout mice studied here have reduction in both vinculin and metavinculin. Based on the current work, it is unclear if reduction in vinculin or metavinculin is predominantly responsible for the observed phenotype. Two recent studies support an important role for metavinculin in cardiac function. Tissue sampled from a patient previously diagnosed with “idiopathic” cardiomyopathy displayed disorganized intercalated disk structures and was found to have a complete absence of metavinculin expression. More recently, three heterozygous metavinculin mutations (two point mutations and one deletion) were found in patients with “idiopathic” dilated cardiomyopathy. While in vitro analysis of these mutants showed that they still bound and cross-linked F-actin like the wild-type metavinculin, F-actin filament organization was disturbed by these mutants. Like the metavinculin deficient patient, histological analysis of a cardiac biopsy from the patient with the metavinculin Arg975Trp mutation displayed abnormal intercalated disks similar to our mice. It must be appreciated though that the analysis of the human sample was performed in a failing heart, while our analyses detailed hearts that had normal physiological function.

Vinculin is present in both cell-to-cell as well as in cell-to-matrix sites. Our results suggest that vinculin is critical component of the cardiac myocyte intercalated disk. Intercalated disks are specialized junctions at the ends of cardiac muscle cells that bond cells to each other, transmit forces of contraction, and provide areas of low electrical resistance for the rapid spread of excitation. Growing evidence has accumulated that ICD alterations are present in cardiac pathologies such as the transition of pressure overload hypertrophy to heart failure or in frankly cardiomyopathic hearts. Only in recent years has direct evidence linked such abnormalities or deficiencies in ICD proteins to cardiomyopathies, suggesting that changes in the ICD may be a primary cause of cardiac pathologies. This premise is illustrated by several mouse models with altered stoichiometry within the ICD, including muscle LIM protein (MLP) knockout mice as well as tropomodulin and cadherin overexpressing mice. Our results also support this concept and indicate for the first time that reduced vinculin expression can predispose the myocardium to progress from compensated hypertrophy to heart failure.

Vinculin may in part stabilize the cardiac myocyte through its indirect linkage to transmembrane integrins. In migratory cells, the recruitment of vinculin to focal adhesions is an early event in strengthening the linkage of ECM to the cytoskeleton. Whether this finding in non-cardiac cells is applicable to myocytes is not fully understood, but it is suggested by our work. In further support of this hypothesis, recent work from our laboratory has shown that a reduction of β1 integrin expression specifically in the cardiac myocyte resulted in abnormal cardiac function. In addition, cardiac myocyte specific dominant-negative disruption of vasodilator-stimulated phosphoprotein (VASP) and mammalian enabled (Mena) from the murine ICD also lead to dilated cardiomyopathy. This is of particular importance, realizing that VASP directly binds to vinculin.

The total ablation of murine vinculin expression results in embryonic lethality with multiple defects including a thin-walled myocardium. Whether this cardiac phenotype in the null mice resulted from a primary or secondary phenomenon is not known. In contrast, the Vin+/− mice we studied had normal development and cardiac function unless stressed. Data from other species and in vitro work both contrast with and support the findings in mice. First, a homozygous vinculin knockout in Drosophila melanogaster leads to viable and fertile flies, even though no stress was placed on the flies. Second, F9 mouse embryonic stem cells, devoid of vinculin, mechanotransduced some biochemical signals, eg, mechanical activation of focal adhesion kinase. Yet, Caenorhabditis elegans vinculin mutants had disorganized muscle, while vinculin was still required for normal cell spreading, motility, adhesion, and morphology. Most importantly, vinculin is necessary for stabilization of focal adhesions and transfer of mechanical forces from the cell membrane to the cytoskeleton through integrins. Furthermore, in vitro antisense suppression of vinculin expression (to approximately 45 ± 20% of wild-type levels) caused disruption of myofibril assembly and alignment in fetal cardiac myocytes. These cell culture results differ from our own and highlight the importance of studies in the intact myocardium.

In summary, we have identified a mouse model with reduced expression of vinculin and metavinculin, which will allow us to gain further insight into the molecular mechanisms which predispose the myocardium to transition from compensated hypertrophy to heart failure. Further work is necessary and ongoing to determine the precise cellular and molecular mechanisms which lead to the phenotypic and physiological results in these heterozygous knockout mice.

Acknowledgments

We thank Drs. Matthew Schibler and Chris Babbit, as well as Michael Huang, for helpful advice and expertise. John Parker (UCLA Cardiovascular Research Laboratories) designed and constructed the optically isolated ECG amplifier. Patricia Reid was invaluable for EM assistance, and Dr. Michael C. Fishbein provided expertise in evaluation of the EM micrographs. The Sharon Tamor Hansen Imaging and Physiology Lab at UCSD was used for de-convolution microscopy with the excellent assistance of Dr. Antine E. Stenbit.
