Apoptosis or programmed cell death is a cellular suicide mechanism that frequently occurs in advanced human atherosclerotic plaques. Caspases, a family of cysteine proteases, have been identified as important effectors of the death machinery. In this study, we report strong caspase-2 immunoreactivity in foam cells of macrophage-origin around the necrotic core of advanced human atherosclerotic plaques. In contrast, smooth muscle cells (SMCs) and macrophages in the fibrous cap as well as endothelial cells, medial SMCs, and SMCs from mammary arteries are negative for caspase-2. Caspase-2-positive macrophages were isolated from human plaques by laser capture microdissection and were then analyzed by Western blotting. A single band of ~35 kd corresponding with the precursor of the short, anti-apoptotic isoform of caspase-2 (caspase-2S) could be identified. Treatment of human U937 macrophages with the DNA strand-breaking agents etoposide or camptothecin stimulated caspase-2S expression. Since atherosclerotic plaques contain a high number of DNA strand breaks, our results provide evidence for a survival factor in macrophage-derived foam cells of human atherosclerotic plaques that might be up-regulated in response to DNA damage. (Am J Pathol 2003, 162:731–736)

Several studies have shown in situ evidence for apoptotic cell death in both animal and human atherosclerotic plaques.1–7 Apoptosis is absent or barely detectable in normal arteries and early atherosclerotic lesions (<0.1% TUNEL-positive nuclei), but is much more pronounced in advanced plaques (1 to 2%).1 All cell types in the plaque are involved, including smooth muscle cells (SMCs), macrophages, and T lymphocytes. Despite many efforts in determining the potential cell death mechanisms, the significance of apoptosis in atherosclerosis remains unclear.4 Recent evidence suggests, however, that apoptotic cell death is a major determinant of the thrombogenicity of the plaque lipid core and a potential contributor to plaque erosion and associated thrombosis.5

The execution phase of apoptosis generally depends on cytoplasmic cysteinyl aspartate-specific proteinases, called caspases, which are synthesized as inactive zymogens.9 The primary structure of procaspases consists of an N-terminal prodomain and two subunits of approximately 10 and 20 kd (p10 and p20 subunit, respectively) which undergo processing to constitute the active enzyme. Once activated, caspases induce intracellular signaling pathways and cleave specific subsets of proteins to evoke the stereotyped sequence of structural changes typical of apoptotic cells. Intracellular proteolytic caspase signaling pathways operate in a network-like fashion so that the initial activation of one caspase can lead to the activation of multiple other family members.10 At present, 14 members of the mammalian caspase family have been identified, several of which display overlapping specificities and apparent redundancy. They can be subdivided into several groups based on phylogenetic analyses and substrate recognition. Human caspase-2, initially described as Ich-1, is unique among the different members of the caspase-family because it has features of both upstream caspases (long prodomain) and downstream caspases (DEXD substrate specificity).11 The prodomain of caspase-2 is essential for oligomerization and autoactivation as well as for nuclear migration and interaction with the death adaptor protein, RAIDD, indicating that caspase-2 could act as an upstream activator of the intracellular caspase cascade.12–14 However, in vitro studies

showed that caspase-2 cannot initiate a wide pro-caspase activation cascade and with the exception of golgin-160, no downstream targets for caspase-2 have yet been found. Alternative splicing of caspase-2 mRNA generates at least two isoforms: procaspase-2L, whose overexpression induces cell death and a truncated variant, caspase-2S, that is devoid of the small subunit (p10) and that has anti-apoptotic potential.11

Previous reports have shown that caspase-1 and -3 colocalize with apoptotic cells in advanced human atherosclerotic plaques.16–17 Since caspase inhibitors have shown promise in preclinical animal models for disorders like traumatic brain injury, amyotrophic lateral sclerosis, and Parkinson’s disease,18 identification of caspases in atherosclerotic plaques might open new perspectives for the development of therapeutic strategies to alter the progression of atherosclerosis. In this study, we show overexpression of caspase-2S in foam cells of macrophage origin around the necrotic core of advanced human atherosclerotic plaques. We also demonstrate that caspase-2S expression can be stimulated in vitro by DNA strand-breaking agents. Since elevated levels of DNA strand breaks can be found in both human and experimental atherosclerosis,19–20 overexpression of caspase-2S in human plaques might be associated with enhanced levels of oxidative DNA damage.

Materials and Methods

Human Carotid Endarterectomy Specimens

Human carotid endarterectomy specimens were obtained from patients with a carotid stenosis of >70%, as demonstrated by digital subtraction angiography and duplex ultrasonography. The specimens were opened along their longitudinal axis and submerged in an alcohol-based fixative. Sonography. The specimens were opened along their longitudinal axis and submerged in an alcohol-based fixative and then embedded in paraffin. Tissue sections (5 μm thick) were deparaffinized in toluol (1 minute), 70% ethanol (1 minute), 90% ethanol (1 minute), and rapidly hydrated with an ethanol gradient [70% ethanol (1 minute), 80% ethanol (1 minute), water (1 minute), and rapidly dehydrated with acetone (2 minutes)].

Slides were stained with hematoxylin and eosin (15 seconds each). The immunohistochemical reactions were carried out by a peroxidase-anti-peroxidase technique.22 TUNEL-staining was combined with an immunohistochemical stain for SC-35 to avoid aspecific labeling.22

Laser Capture Microdissection (LCM)

Ten-μm thick sections of carotid endarterectomy specimens were mounted on Optiplus slides (Biogenex, San Ramon, CA) and deparaffinized in toluol (2 × 3 minutes). Slides were washed with isopropanol (1 minute), 70% ethanol (1 minute each), water (1 minute), and rapidly stained with hematoxylin and eosin (15 seconds each). Next, sections were washed with water (1 minute), dehydrated with an ethanol gradient [70% ethanol (1 minute), 90% ethanol (1 minute), 100% ethanol (2 × 1 minute)], washed with xylene (5 minutes), and air dried (20 minutes). Caspase-2 immunoreactive areas were microdissected from 10 tissue sections using the Pixcell II LCM system (Arcturus Engineering Inc., Mountain View, CA). An adjacent immunostained section was used as a guide for the microdissection (navigated-LCM).

Protein Isolation and Immunoblot Assays of Microdissected Cells

Microdissected cells were lysed by adding 20 μl of Laemmli sample buffer (BioRad, Richmond, CA) to the LCM
caps. Cell lysates were heat denatured for 5 minutes and loaded on a 12.5% sodium dodecyl sulfate (SDS)-polyacrylamide gel. Western blotting to Hybond-enhanced chemiluminescence membranes (Amersham Pharmacia Biotech, Rainham, UK) was performed according to standard procedures. Antibody detection was accomplished with SuperSignal West Pico chemiluminescent substrate (Pierce, Rockford, IL). Signals were visualized using a Lumi-imager (Roche Diagnostics, Mannheim, Germany). Long-term exposures (30 minutes) and 2\(^2\) binning settings (ie, conversion of four adjacent pixels to one “super” pixel) were applied to enhance sensitivity.

**Results**

**Overexpression of Caspase-2S in Human Atherosclerotic Plaques**

Strong immunoreactivity for caspase-2 was found in foam cells of macrophage-origin (CD68-positive cells) around the necrotic core of advanced human atherosclerotic plaques (thin fibrous cap atheromata of carotid endarterectomy specimens) (Figure 1). Caspase-2 immunoreactivity was found both in the cytoplasm and nucleus of the labeled cells. Cells from the fibrous cap including macrophages and SMCs as well as endothelial cells, medial SMCs, and SMCs from mammary arteries were negative for caspase-2. We also found that some CD68-positive cells in the necrotic core were caspase-2-negative. To determine whether the proapoptotic isoform caspase-2L or the truncated anti-apoptotic variant caspase-2S was up-regulated, caspase-2-positive cells were isolated from the plaque by laser capture microdissection (Figure 2, A and B). After SDS-PAGE and Western blotting, we were able to detect a single band of \(\sim 35 \) kd which corresponds with caspase-2S (Figure 2C). The procaspase-2L precursor (48 kd) or cleaved fragments of procaspase-2L could not be identified. Extracts from microdissected regions of the plaque that were negative for caspase-2 did not reveal detectable amounts of caspase-2 on Western blots, neither caspase-2S nor procaspase-2L. When carotid endarterectomy specimens were stained for procaspase-2L, macrophages around the necrotic core were negative, suggesting that the anti-

apoptotic isoform is up-regulated. Moreover, caspase-2S immunoreactive macrophages did not show signs of apoptotic cell death (cleaved caspase-3-negative, Figure 2C) and were not labeled by the TUNEL technique.

Up-Regulation of Caspase-2S in U937 Macrophages

Because the DNA strand-breaking agent etoposide can induce expression of caspase-2 and -3 genes in human tumor cells,23 U937 macrophages were treated with etoposide and with a related DNA-damaging compound, camptothecin, for up to 24 hours. In both cases, apoptotic cell death occurred within 6 hours of treatment as shown by the activation of caspase-3, cleavage of poly(ADP-ribose) polymerase-1 (PARP-1) (Figure 3, A and B) and the appearance of apoptotic bodies (not shown). Expression of PARP-1 was up-regulated, especially in cells that were treated with etoposide. Apoptotic cell death was associated with cleavage of procaspase-2L into active p20 fragments (Figure 3, A and B). This resulted in a progressive loss of procaspase-2L levels during treatment. We also observed the intermediate proteolytic fragment p33 consisting of the prodomain and p18 subunit (Figure 3, A and B). In contrast to procaspase-2L, caspase-2S was up-regulated in response to the cytotoxic effects of etoposide and camptothecin. Elevated levels of caspase-2S protein were detectable after 2 hours of treatment (Figure 3, A and B). At this time point, the majority of cells were not in the execution phase of apoptosis as cleavage of caspase-3 and its substrate PARP-1 did not occur. Due to rapid cell death, caspase-2S could not be detected when cells were incubated for longer than 2 hours. U937 cells treated with a cocktail of the pro-inflammatory cytokines TNF-α and IFN-γ initiated apoptotic cell death, but did not up-regulate caspase-2 isoforms, even after 4 days of treatment (data not shown). This suggests that apoptotic U937 cells do not necessarily up-regulate caspase-2S expression to prevent cell death.

**Discussion**

Caspases are cysteine proteases that play an essential role in apoptosis by cleaving several key cellular proteins.9 In this study, we found overexpression of the short isoform of caspase-2 (caspase-2S) in foam cells of macrophage origin around the necrotic core of advanced human atherosclerotic plaques. Both cytoplasmic and nuclear staining could be observed. This is in accordance with subcellular localization studies of procaspase-2L which has been found in the Golgi apparatus and intermembrane space of mitochondria as well as in the nucleus of viable cells.12,24,25 The intracellular localization of caspase-2S is currently unknown but could be similar.

In contrast to procaspase-2L, caspase-2S behaves like an endogenous inhibitor of apoptotic cell death.\(^{11,26}\) Indeed, overexpression of caspase-2S can inhibit nuclear changes associated with apoptotic cell death.\(^{26}\) Caspase-2S also prevents the maturation of apoptotic bodies, delays phosphatidylserine externalization on the plasma membrane of dying cells and prevents cleavage and activation of procaspase-2L.\(^{26}\) Therefore, it is conceivable that caspase-2S immunoreactive cells in human atherosclerotic plaques are TUNEL-negative and do not contain active caspase-3. However, cleavage of procaspase-3, procaspase-7, and poly(ADP-ribose) polymerase as well as the fragmentation of nuclear DNA are not affected in caspase-2S overexpressing cells, suggesting that caspase-2S only interferes with selective features of apoptosis.\(^{26}\)
In comparison with monocytes, activated macrophages are resistant to numerous death stimuli, including death receptor ligation, anti-neoplastic agents, and ionizing radiation. This suggests up-regulation of survival factors during macrophage differentiation. At present, the mechanisms responsible for macrophage resistance to apoptosis and persistence in pathological conditions are poorly understood. Perlman et al demonstrated that overexpression of FADD-like ICE (FLICE)-inhibitory protein in macrophages confers resistance to Fas-mediated apoptosis. Other studies suggest that macrophages develop several anti-apoptotic mechanisms by uptake of oxLDL or agLDL. Importantantly, enhanced caspase gene expression is not a frequent event because caspases are regulated predominantly via post-translational mechanisms such as cleavage of the precursor enzyme and subcellular relocalization. However, the DNA-damaging agent etoposide can increase caspase-2 and -3 expression in various human tumor cells. Etoposide is a cytotoxic drug that complexes with topoisomerase II and DNA to enhance double-strand and single-strand DNA breaks. According to recent evidence, caspase-2L seems to provide an important link between caspase-2L-induced DNA damage, cytochrome C release from the mitochondria, and cleavage of procaspase-9 and -3. Since procaspase-2L needs an adaptor molecule for activation, it is possible that etoposide-induced activation of procaspase-2L triggers the formation of a nuclear signaling complex. In the present study, we could demonstrate overexpression of caspase-2S when U937 macrophages were treated with the DNA-damaging agents, etoposide and camptothecin. Up-regulation of caspase-2S was only evident in the early stages of treatment, ie, before cells entered the execution phase of apoptosis. This implicates that caspase-2S is rapidly degraded during cell death. Recently, we observed an extensive formation of DNA strand breaks in both human and experimental atherosclerotic plaques using single cell gel electrophoresis assays. Since this method requires cell lysis and removal of the cytoplasmic content, a direct relation between DNA strand breaks and caspase-2S overexpression in human plaques cannot be determined. However, DNA strand break formation was associated with the up-regulation of several DNA repair enzymes including poly(ADP-ribose) polymerase 1 (PARP-1). The latter enzyme is activated by DNA strand breaks to participate in DNA repair and is predominantly expressed in macrophage-derived foam cells of advanced atherosclerotic lesions. Around the necrotic core of human plaques, macrophages also express inducible nitric oxide synthase and contain large amounts of nitrotyrosine and oxidized lipids. Therefore, overexpression of caspase-2S and oxidative DNA damage in human plaques may be coherent events, especially in macrophages that are subjected to high levels of oxidative stress. It is important to note that intracellular reactive oxygen species (ROS) are key players in oxidative tissue injury of human plaques, including the formation of DNA strand breaks, so that free radical attack of DNA may be a potential underlying cause of caspase-2S overexpression. However, in contrast to etoposide and camptothecin, a direct in vitro link between ROS and caspase-2S gene expression remains difficult to prove as ROS modulate a variety of signaling pathways in which many gene products are involved. It is currently unknown how DNA strand breaks induce alternative splicing yielding high levels of caspase-2S transcript. Caspase-2L is derived from the skipping of alternative exon 9 in the pre-mRNA whereas
caspase-2S is a truncated version of the protein due to inclusion of exon 9 (containing a premature termination codon). Recent evidence suggests that the polypyrimidine track-binding protein (PTB/hnRNP I) binds downstream of the alternative exon 9, thereby preventing exon 9 inclusion and caspase-2S formation. Possibly, DNA strand breaks affect the activity of PTB/hnRNP I or modulate its subcellular localization.

Taken together, our data indicate that the short anti-apoptotic isoform of caspase-2 is up-regulated in macrophage-derived foam cells around the necrotic core of human atherosclerotic plaques. Since DNA-damaging agents cause caspase-2 up-regulation in vitro, caspase-2S may act as a nuclear sensor to detect DNA strand breaks and may help macrophages to survive increased levels of oxidative DNA damage. This hypothesis supports the concept that macrophages in the interior of atheroma lesions need mechanisms to cope with various cytotoxic plaque components such as oxidized lipids and free radicals that may cause dysfunction and, possibly, death of the inflammatory cells.
