Recent studies suggest that expression of cyclooxygenase-2 (Cox-2) is elevated in transitional cell carcinoma (TCC) of the urinary bladder and that inhibition of Cox-2 activity suppresses bladder cancer in experimental animal models. We have investigated the expression of Cox-2 protein in human TCCs (n = 115), in situ carcinomas (Tis) of the urinary bladder (n = 17), and in nonneoplastic urinary bladder samples (n = 16) using immunohistochemistry. Cox-2 immunoreactivity was detected in 66% (67 of 102) of the carcinomas, whereas only 25% (4 of 16) of the nonneoplastic samples were positive (P < 0.005). Cox-2 immunoreactivity localized to neoplastic cells in the carcinoma samples. The rate of positivity was the same in invasive (T1–3; 70%, n = 40) and in noninvasive (Tis and Ta; 65%, n = 62) carcinomas, but noninvasive tumors had a higher frequency (32%) of homogenous pattern of staining (>90% of the tumor cells positive) than the invasive carcinomas (10%) (P < 0.05). However, several invasive TCCs exhibited the strongest intensity of Cox-2 staining in the invading cells, whereas other parts of the tumor were virtually negative. Finally, strong Cox-2 positivity was also found in nonneoplastic ulcerations (2 of 2) and in inflammatory pseudotumors (2 of 2), in which the immunoreactivity localized to the nonepithelial cells. Taken together, our data suggest that Cox-2 is highly expressed in noninvasive bladder carcinomas, whereas the highest expression of invasive tumors associated with the invading cells, and that Cox-2 may also have a pathophysiological role in nonneoplastic conditions of the urinary bladder, such as ulcerations and inflammatory pseudotumors. (Am J Pathol 2001, 158:849–853)
Furthermore, NSAIDs that inhibit either preferentially or selectively Cox-2 are chemopreventive against bladder cancer in the rat.\(^{10,11}\) Elevated Cox-2 expression has been described in several human malignancies.\(^{5,7,12}\) However, in the case of bladder cancer, the data are inconsistent in respect of the presence of Cox-2 expression in in situ carcinomas (Tis), and whether Cox-2 is expressed in low-grade and in noninvasive TCCs.\(^ {13-15}\) The purpose of this study was to investigate the expression of Cox-2 in both noninvasive and invasive TCC and in nonneoplastic lesions of the bladder using immunohistochemistry and a Cox-2-specific monoclonal antibody combined with the use of appropriate control experiments.

Materials and Methods

Patient Samples

Formalin-fixed and paraffin-embedded urinary-bladder tissue specimens from patients with invasive TCC (T1, T2, and T3; \(n = 40\)), noninvasive carcinomas (Tis or Ta; \(n = 62\)), and 16 nonneoplastic conditions (eight cystitis, two ulcerations, two inflammatory pseudotumors, and four samples with normal histology) were obtained from the files of the Department of Pathology, Helsinki University Central Hospital (Table 1). The age of the carcinoma patients was 71 ± 13 years (mean ± SD; range, 42 to 95 years) and that of patients with nonneoplastic lesions 67 ± 18 years (range, 25 to 94 years). Of the TCC patients 25 were women and 77 men, and in the nonneoplastic group there was three women and 13 men. Twenty of the specimens were taken at radical cystectomy and the rest were transurethral biopsies. Grade (G1–3) of the tumor was determined according to the World Health Organization classification,\(^ {16}\) and by the more recent (low and high grade) World Health Organization/International Society of Urologic Pathologists consensus classification for the urothelial neoplasms.\(^ {17}\) All samples were reassessed by a pathologist (SN).

Immunohistochemistry

The specimens were sectioned (4 \(\mu\)m), deparaffinized, and microwaved for 4 × 5 minutes at 700 W in 0.01 mol/L Na-citrate buffer (pH 6.0) for antigen retrieval. The slides were then immersed in 0.6% hydrogen peroxide in methanol for 30 minutes to block endogenous peroxidase activity and in blocking solution [1:5:100 normal horse serum in phosphate-buffered saline (PBS)] for 15 minutes to block unspecific binding sites. Immunostaining was performed with Cox-2-specific anti-human monoclonal antibody (160112; Cayman Chemical Co., Ann Arbor, MI) in a dilution of 1:200 (2.5 \(\mu\)g/ml) in PBS containing 0.1% sodium azide and 0.5% bovine serum albumin at room temperature overnight. Then the sections were treated with biotinylated horse anti-mouse immunoglobulin (1:200; Vector Laboratories Inc., Burlingame, CA) and avidin-biotin peroxidase complex (Vectastain ABComplex, Vector Laboratories). The peroxidase staining was visualized with 3-amino-9-ethylcarbazole (Sigma Chemical Co., St. Louis, MO), and the sections were counterstained with Mayer’s hematoxylin. The specificity of the antibody was determined by pre-adsorption of the primary antibody with human Cox-2 control peptide (1 to 10 \(\mu\)g/ml, Cayman Chemical) for 1 hour at room temperature before the staining procedure. An \(\alpha\)-smooth muscle cell actin peptide (50 \(\mu\)g/ml; DAKO, Glostrup, Denmark) was used as a non-Cox-2 peptide.

The intensity of the Cox-2 immunoreactivity was graded negative, weakly positive, or strongly positive, reflecting both the intensity of staining as well as the amount of positive cells in consensus of two investigators (SN and AR). In addition, the proportion of Cox-2-positive tumor cells was estimated (<10%, 10 to 90%, >90%).

Statistical Analysis

Statistical significance was calculated using the Fisher’s exact test, and \(P < 0.05\) was selected as the statistically significant value.

Results

Expression of Cox-2 protein was investigated in 102 carcinoma specimens and in 16 nonneoplastic samples of the human urinary bladder using immunohistochemistry (Figure 1). Cox-2 immunoreactivity was detected in 66% (67 of 102) of the carcinomas (Table 1), whereas only
25% (4 of 16) of the nonneoplastic samples were positive ($P < 0.005$). Cox-2 immunoreactivity localized almost exclusively to the neoplastic cells in the TCCs, whereas the stroma of the tumors was negative (Figure 1, G to L). Although 19% of the TCC specimens stained with high intensity, none of the nonneoplastic specimens showed strong staining in the epithelial cell compartment. The rate of positivity was the same in invasive (T1–3; 70%, $n = 40$) and in noninvasive (Tis or Ta; 65%, $n = 62$) TCCs. However, only 24% (24 of 102) of the TCCs exhibited homogenous staining (>90% of the tumor cells positive), suggesting that the staining pattern of Cox-2 is relatively heterogeneous. Interestingly, noninvasive specimens exhibited a higher frequency (32%, 20 of 62) of homogenous staining than the invasive TCCs (10%, 4 of 40) ($P < 0.05$). Furthermore, several invasive TCCs exhibited the strongest intensity of Cox-2 staining in the invading cells (1 of 45 of T1, 2 of 12 of T2, and 4 of 7 of T3), whereas other parts of the tumor expressed low or undetectable levels of the protein. No statistically significant difference in the Cox-2 positivity was found between different grades of the TCCs when either World Health Organization classification (Table 1) or World Health Organization/ISUP consensus classification were used (low-grade tumors were 61% and high-grade neoplasms 69% positive for Cox-2). In addition to the neoplastic epithelial cells of the TCCs, strong Cox-2 positivity was present at sites of nonneoplastic ulcerations (2 of 2) and in inflammatory pseudotumors, in which the immunoreactivity localized to the nonepithelial cells (Figure 1, M to P). The pattern of the Cox-2 immunoreactivity in both neoplastic and nonneoplastic cells was of diffuse cytoplasmic type with occasional perinuclear staining (Figure 1; G, I, and L). The specificity of the monoclonal antibody was confirmed by staining the specimens with and without preadsorption with the antigenic peptide, which blocked virtually all immunoreactivity obtained by the antibody (Figure 1 and data not shown). A peptide unrelated to Cox-2 did not reduce the immunoreactivity obtained by the monoclonal antibody.

**Discussion**

Our data indicate that Cox-2 is expressed in 65% of human TCCs (Ta and T1–4) as detected by immunohistochemistry. The Cox-2 immunoreactivity localized to the neoplastic cells, whereas the tumor stroma was negative.
Importantly, all immunoreactive signal obtained by the Cox-2-specific monoclonal antibody was blocked by the antigenic Cox-2 peptide, but not by an unrelated peptide. Our data are consistent with previously published reports that indicate that 34 to 84% of TCCs are positive for Cox-2 as detected by immunohistochemistry or immunoblotting. Furthermore, it has been reported that no Cox-2 expression is evident in nonneoplastic epithelium of the human, rodent, or canine urine bladder, although one report indicated a relatively high frequency (53%) of Cox-2 expression in nonneoplastic epithelium adjacent to the tumor. We found that the normal transitional cell epithelium was virtually negative for Cox-2 in both nonneoplastic and neoplastic specimens. However, we did find strong expression of Cox-2 at sites of nonneoplastic ulcerations and in inflammatory pseudotumors, but in contrast to the carcinomas, this injury- and inflammation-associated Cox-2 expression localized to the nonepithelial (inflammatory and connective tissue) cells. Thus, although the stroma of the bladder carcinomas was negative for Cox-2, we were able to detect Cox-2 expression in the stromal cells when they were appropriately activated. Because expression of Cox-2 has been associated with ulcer healing in the gastrointestinal tract and its expression is enhanced by various proinflammatory agents, expression of Cox-2 in nonneoplastic bladder lesions may be related to healing processes present at the site of ulceration and because of inflammatory activity in pseudotumors. The chemopreventive effect of NSAIDs may be targeted to early lesions, because they induce regression of premalignant colorectal polyposis in patients with familial adenomatous polyposis and in experimental animal models of this disease. Cox-2 is also expressed in epithelial cells of preneoplastic dysplasias and in situ carcinomas of the stomach (unpublished results), esophagus, and lung. Furthermore, it is expressed in chemically induced preneoplastic lesions of the lung and in the urinary bladder of the rat. However, although it is the carcinoma cells that express the highest level of Cox-2 in colorectal cancer, Cox-2 seems to localize to the stromal and to a lesser extent to the epithelial cells in colonic adenomas. We found that Cox-2 is expressed in 71% of the Tis and in 60% of the Ta carcinomas. This is consistent with data published by Mohammed and colleagues and by Shirahama, who found 75 and 93% of Tis carcinomas to be positive for Cox-2 as detected by immunohistochemistry and by immunoblotting, respectively. However, our data differ from those published by Kömhoff and colleagues, who did not detect any Cox-2 expression in noninvasive (Ta) or low-grade TCCs. In fact, we found a higher frequency of homogenous Cox-2 staining in the Tis and Ta tumors compared to the invasive carcinomas. Discrepancies of the immunohistochemistry data may depend on the use of different antibodies and/or staining methods that affect both sensitivity and specificity. A more detailed description about the performance of different Cox-2 antibodies is beyond the scope of this paper. However, in respect of invasive carcinomas, we did find expression of Cox-2 to be high in invading cells of the invasive tumors, even when the rest of the tumor is negative for Cox-2. Interestingly, expression of Cox-2 may be related to invasion and metastasis of carcinomas, which could potentially be connected to increased production and activation of matrix metalloproteinases as shown by overexpression of Cox-2 in cancer cell lines.
