Differences between Squamous Cell Carcinoma and Keratoacanthoma in Angiotensin Type-1 Receptor Expression

Hikaru Takeda and Shigeo Kondo

Angiotensin II receptors are the specific receptors of angiotensin II of the renin-angiotensin system. The existence and role of the receptors in the skin have not been determined. We immunohistochemically studied the expression of angiotensin receptors in the human skin. The results demonstrated the expression of angiotensin type 1 receptor (AT1) in the normal human suprabasal epidermis. The expression pattern suggests the role of AT1 in association with differentiation. In addition, we studied the expression of AT1 in squamous cell carcinoma (SCC) of the skin, SCC of the lip, and keratoacanthoma (KA). Our experiments showed that high, intermediate, and low levels of AT1 were observed in 37 (74.0%), 7 (14.0%), and 2 (4.0%) of 50 cases of SCC of the skin, respectively, and the negative periphery pattern was observed in 17 (77.3%) of 22 cases of KA. These observations suggest that the immunohistochemical study of AT1 is useful to distinguish SCC from KA. Studying the role and distribution of AT1 may help in understanding the pathophysiology of the skin. (Am J Pathol 2001, 158:1633–1637)

Materials and Methods

Cases

A total of 50 cases of SCC of the skin and 14 cases of SCC of the lip were selected from a consecutive series of 69 cases diagnosed and treated for SCC at Yamagata University Hospital, Japan between 1978 and 1999 by excluding cases with insufficient tumor material (n = 5). All 22 cases that were diagnosed and treated for KA at the hospital between 1978 and 1999 were also studied. Normal back skin from a 38-year-old Japanese woman, normal lip from a 64-year-old Japanese man, and normal brain tissue from a 33-year-old man were used as normal controls.

Accepted for publication January 30, 2001.

Histology

Five-μm-thick paraffin-embedded tissue sections of all tumors were stained with hematoxylin and eosin (H&E). Histological typing and grading of SCCs were re-evaluated for this study according to Lever’s classification.11

Immunohistochemistry

The specimens were fixed in 10% formalin and embedded in paraffin by routine procedures. Five-μm sections were cut for immunohistochemical investigation using the labeled streptavidin-biotin method as described previously.12 The primary antibodies used in this study were anti-angiotensin type-1 (affinity-purified rabbit polyclonal anti-human AT1; Santa Cruz, Santa Cruz, CA) and type-2 receptor antibodies (affinity-purified goat polyclonal anti-human AT2; Santa Cruz). Briefly, endogenous peroxidase was blocked by incubating deparaffinized sections in 0.3% hydrogen peroxide in methanol. The sections were washed in phosphate-buffered saline (PBS), pH 7.2, then incubated for 15 minutes at room temperature with defatted milk to block nonspecific reactions to the antibodies. The sections were subsequently incubated overnight at 4°C with primary antibodies and washed in PBS. After incubation with a mixture of biotinylated anti-rabbit immunoglobulin goat serum (DAKO, Carpinteria, CA) for anti-AT1 antibody and anti-goat immunoglobulin rabbit serum (DAKO) for anti-AT2 antibody, respectively, for 20 minutes at room temperature, the sections were then rewash in PBS, and incubated with peroxidase-conjugated streptavidin (DAKO) for 20 minutes at room temperature. Then they were washed again in PBS and the reaction was visualized using 3,3′-diaminobenzidine tetrahydrochloride solution (0.2 mg/ml) containing 0.005% hydrogen peroxide. Sections were subsequently washed in water, counterstained with 1% methyl green, dehydrated, cleared, and mounted. Negative controls using normal rabbit and goat serum instead of the individual primary antisera were stained by the same procedures. Normal skin and brain tissues were used as positive controls for AT1 and AT2, respectively.

Evaluation of the Stainings with AT1

In cases of SCC of the skin, SCC of the lip, and KA, the percentage of AT1-positive tumor cells of all neoplastic cells in the section was estimated and graded into one of three categories: low (<35%), intermediate (35 to 75%), or high (>75%). Among the cases that were graded high, there was a group of cases that showed a distinct staining pattern. In this pattern, 1 to 2 layers of the tumor cells that were located at the periphery of the tumor nest stained negatively. This pattern was termed as “negative periphery” and was graded as one category independent of the other three categories that showed no particular arrangement of AT1-positive cells.

Results

AT1

Normal Human Skin

In the interfollicular epidermis, the suprabasal epidermis stained positive with AT1, but the basal layer was negative (Figure 1). In the suprabasal epidermis, cell membrane was positive, but nuclei were not. As to the infundibulum of a hair follicle, the suprabasal layers of the outer root sheath were all positive, and continued to the interfollicular, suprabasal epidermis. The basal layer of the outer root sheath was negative and continued to the basal layer of the interfollicular epidermis. Original magnification, ×33.

Normal Lip

In the vermilion border, unlike the normal epidermis, the upper 2 to 3 layers of the epithelium stained positive.
with AT1, but the other layers of the epithelium including the basal layer were negative (Figure 2).

**SCC of the Skin**

On the whole, high, intermediate, and low levels of AT1 were observed in 37 (74.0%), 7 (14.0%), and 2 (4.0%) of all 50 cases, respectively (Figure 3; A, B, and C and Table 1). Four cases (8.0%) showed negative periphery pattern (Figure 3D). In these four cases, the periphery of the tumor nests was composed of less-keratinized tumor cells in H&E stain.

**KA**

In 17 cases (77.3%), the tumor showed a negative periphery pattern (Figure 4). In a typical case, the eosinophilic and keratinizing cells with a glassy appearance at the center of the lobules in H&E stain were AT1-positive. However, the one or two layers of basophilic, nonkeratinized cells at the periphery of the lobules were negative. In some of the nests that were located at the periphery of the tumor, most of the tumor cells were AT1-negative. In five cases (22.7%), tumors did not show a negative periphery pattern.

High, intermediate, and low levels of AT1 were observed in 3 (21.4%), 3 (21.4%), and 6 (42.9%) of all 14 cases, respectively (Table 2). Two cases (14.3%) showed a negative periphery pattern.

Angiotensin Type 2 Receptor

All specimens were negative with anti-AT2 antibody.

Discussion

AngII exerts the effects through its specific receptors. Currently, two main angiotensin-receptor subtypes, AT1 and AT2, which display a heterogeneous distribution in peripheral tissues and brain, have been characterized. Our immunohistochemical study demonstrated the expression of AT1 in the normal human skin and the skin tumors. The classical role of AngII in regulating blood pressure is mediated by AT1. In addition, the promoting effects of AngII for cell proliferation and extracellular matrix production have been recently attributed to AT1. However, in the epidermis, the notion of a trophic effect of AT1 activation seems difficult to apply. AT1 expression was found in the squamous cell layer and the granular layer but not detected in the basal cell layer. The expression pattern is the same with that of keratin 10. In the normal epidermis, commitment to differentiation of basal cells is accompanied by a switch in keratin gene expression from keratins 5 and 14 to 1 and 10, and keratin 10 is presumed to be a marker of differentiation. Furthermore, keratinocyte proliferation by AngII is mediated through a non-AT1, non-AT2 AngII receptor. Taken together, the possible roles of angiotensin receptors in human keratinocytes are presumed as AT1 in differentiation and a non-AT1, non-AT2 receptor in proliferation.

SCC of the skin is generally believed to originate from the normal squamous cells that are located in the suprabasal epidermis. In our experiments, the suprabasal epidermis stained positive with AT1, and 37 cases (74.0%) of 50 cases were graded as high in terms of immunostaining pattern of AT1. These results seem to reflect the belief of suprabasal origin of SCC. In well-differentiated SCC, high, intermediate, and low levels of AT1 were observed in 17 (81.0%), 3 (14.3%), and 0 (0.0%) of the 21 cases, respectively. In moderately differentiated SCC, high, intermediate, and low levels of AT1 were observed in 18 (72.0%), 4 (16.0%), and 1 (4.0%) of the 25 cases, respectively. In poorly differentiated SCC, high, intermediate, and low levels of AT1 were observed in 0 (0.0%), 0 (0.0%), and 1 (50.0%) of the two cases, respectively. The negative periphery pattern was found only in 4 (8%) of 50 cases. This pattern seems to appear when tumor cells located at the periphery of tumor nests show less keratinization even if the center of the nests is well keratinized.

On the other hand, KA, which is a benign skin tumor, often resembles well-differentiated or moderately differentiated SCC clinically and histologically. In some cases, KA shows a greater degree of nuclear atypia than do some SCCs, and this makes the differentiation of two diseases very difficult. It is generally believed that KA has its origin in the infundibulum of one or several hair follicles. In the infundibulum of the hair follicle, the suprabasal layers stained positive and the basal cell layer stained negative. Our experiments showed that 17 cases (77.3%) of all 22 cases were graded as negative periphery. These observations seem to reflect the infundibular origin of KA. The results of immunostaining of SCC and KA demonstrated a striking contrast. Our experiments indicate that the immunohistochemical study of the expression of AT1 assists one to distinguish SCC from KA.

In the epithelium of normal lip, positive staining of AT1 was found only in the uppermost 2 to 3 layers. This finding may be a result of less keratinization of the lip epithelium, because the normal lip epithelium shows less granular layer and horny layer than the epidermis of the skin does. In SCC of the lip, on the whole, high, interme-

* Percentage of AT1-positive cells of tumor cells in the specimen.
diate, and low levels of AT1 were observed in 3 (21.4%), 3 (21.4%), and 6 (42.9%) of 14 cases, respectively. The percentage of AT1-positive cells of the tumor cells is low compared to that of SCC of the skin, even in well-differen-
tiated or moderately differentiated types. This relatively low percentage may reflect less immunoreactivity with AT1 of the normal lip epithelium.

Our experiments revealed the expression and distribution of AT1 in the normal epidermis, lip, and the skin tumors. The results of our study suggest that the immu
nohistochemical study of AT1 is helpful in distinguishing SCC from KA and in understanding the pathophysiology of the skin and skin tumors.
