Matrix metalloproteases (MMPs) are a group of zinc-dependent endopeptidases that can degrade every component of the extracellular matrix. Under normal circumstances, the levels of MMPs are tightly regulated at both transcriptional and posttranscriptional levels. However, they are up-regulated in pathological states such as inflammation. Previous investigations have suggested that MMP-12 (metalloelastase) may be an important mediator in the pathogenesis of chronic lung injury. In this study we investigated the role of metalloelastase in the pathogenesis of acute lung injury using mice containing a targeted disruption of the metalloelastase gene. Neutrophil influx into the alveolar space in metalloelastase-deficient animals was reduced to 50% of that observed in parent strain mice following the induction of injury by immune complexes. In addition, lung permeability in metalloelastase-deficient mice was 50% of that of injured parent strain animals with normal levels of metalloelastase and this was correlated with histological evidence of less lung injury in the metalloelastase-deficient animals. Collectively, the data suggest that metalloelastase is necessary for the full development of acute alveolitis in this model of lung injury. Further, the data suggest that reduced injury in metalloelastase-deficient mice is due in part to decreased neutrophil influx into the alveolar space. (Am J Pathol 2001, 158:2139–2144)

Materials and Methods

Metalloelastase-Deficient Mice

Mice possessing a homozygous deletion of exons 1 and 2 of metalloelastase9,10 were kindly provided by Dr. Steven Shapiro of the Departments of Medicine and Cell Biology at the Washington University School of Medicine (St. Louis, MO). They were bred and maintained on a diet which inhibit all MMP activities, and studies with TIMPs suggest a role for MMPs (as a group) in the pathophysiology of acute lung inflammation.7 Recently, mice with genetic deletions of individual MMPs have been developed. It is hoped that the use of these animals will facilitate the understanding of the roles of individual MMPs in disease pathophysiology.

Murine metalloelastase is a 22-kd (active form) member of the MMP family.8,9 This enzyme, the primary elastase enzyme of the macrophage, can hydrolyze a broad spectrum of extracellular matrix and has been shown to be necessary for macrophage-mediated proteolysis of the extracellular matrix during invasion.10 Previous studies have also suggested that metalloelastase may be necessary for disease development in a murine model of emphysema,11 and it has been implicated in the pathogenesis of human abdominal aortic aneurysms and rabbit aortic lesion development.12 The engineering of a mouse strain deficient in metalloelastase facilitated the investigation of the specific role of this MMP in an acute immune complex-mediated murine model of lung injury. Because previous studies suggested a role for metalloelastase in chronic inflammatory injury, we used metalloelastase-deficient mice to explore what role this enzyme may play in a model of acute lung injury induced by immune complexes. Because other MMPs, such as gelatinase B, are also up-regulated in acute lung injury7 and no selective metalloelastase inhibitors are available, the use of these metalloelastase-deficient mice allows for the precise delineation of the role of metalloelastase in the complex pathophysiology of the acute lung injury process.

129SvEv background. Mice used in these studies were 5 to 9 weeks of age and housed under specific pathogen-free conditions.

**IgG Lung Injury Model**

All procedures involving animals were performed following review and approval by the University Committee on Use and Care of Animals (University of Michigan, Ann Arbor, MI). The immune complex-induced lung injury model is described in recent publications. Mice were anesthetized with a mixture (9:1 v/v) of ketamine and xylazine (Fort Dodge Labs, Fort Dodge, IA). Tracheotomies were performed and 60 μl of a 5 mg/ml rabbit anti-bovine serum albumin (BSA) antibody solution was instilled into the lungs. In addition, 100 μl of a 2.5 mg/ml BSA solution was introduced intravenously. Animals were sacrificed after 4 hours by interperitoneal injection of 2 mg/kg ketamine. They were then exsanguinated and their thoracic cavities opened to expose the lungs and trachea. A Leur-lok syringe with a 21-gauge needle was then fed into a tracheal incision and secured with a suture, and lungs were initially lavaged with 0.7 ml of sterile saline. The retrieved bronchoalveolar lavage (BAL) fluid from this lavage was centrifuged to remove cells, subsequently used for zymograms, and the protein quantified for permeability analysis. The lungs were then repeatedly lavaged with a total of 2 ml of sterile phosphate-buffered saline (PBS). Cell pellets obtained from all lavages were resuspended in PBS (pH 7.5) and counted using a hemocytometer.

**Western Blot Analysis**

A rabbit polyclonal antibody raised against the catalytic region of metalloelastase (Dr. Steven Shapiro, Washington University School of Medicine) was used to probe a blot containing proteins from 30 μl of murine macrophage culture fluid from saline treated 129SvEv parent strain and metalloelastase-deficient mice. The blot was blocked by incubating it in 1 × T-TBS [Tween-Tris buffered saline; 1.5 mol/L NaCl, 10 mmol/L Tris, 1% Tween 20, 5% (w/v) nonfat dried milk]. It was then exposed to a polyclonal antibody raised against the catalytic region of metalloelastase (Dr. Steven Shapiro, Washington University) in T-TBS. Autoradiography was facilitated by using Phototope (New England Biolabs, Beverly, MA) reagents following the manufacturer’s protocol.

**Substrate-Embedded Enzymography**

SDS-PAGE substrate-embedded enzymography (zymography) was used to assess gelatinase A (MMP-2) and gelatinase B (MMP-9) activities. Briefly, SDS-PAGE gels were prepared from 30:1 acrylamide:bis, with the incorporation of gelatin (1 mg/ml) before casting. The gelatin gels were routinely 7.5% acrylamide, with the final concentrations of the other components of the gels as follows: 325 mmol/L Tris-HCl (pH 8.8), 0.1% SDS, 0.05% ammonium persulfate, and 0.05% TEMED. Denatured but non-reduced samples and standards were then electrophoresed at constant voltage of 150 V in an ice bath under non-reducing conditions. Gels were removed and subjected to the following wash protocol: twice for 15 minutes in 50 mmol/L of Tris buffer (pH 7.4) containing 1 mmol/L Ca^{2+} and 0.5 mmol/L Zn^{2+} with 2.5% Triton X-100; and once for 5 minutes in Tris buffer alone. Gels were incubated overnight in Tris buffer with 1% Triton X-100 and stained with Coomassie brilliant blue 250-R. Zones of enzyme activity were scanned and quantitated. A volume of 25 μl of undiluted specimen (BAL fluid) was used for this assay.

**Permeability Measurement**

After injury, BAL fluids (described above) from parent strain and metalloelastase gene-deleted mice were used to assess lung vasculature permeability. Total protein content was assayed by BCA protein assay. Briefly, samples were diluted and BAL protein levels were determined for injured and control animals using the BCA protein assay (Pierce, Rockford, IL) and compared to a BSA standard curve. Protein concentration was determined using a BSA standard curve.

**Histology**

Four hours after induction of the lung injury, mice were sacrificed and the lungs, heart, and associated vasculature were removed en bloc. The lungs were inflated with 4% paraformaldehyde, embedded in paraffin, and 5-μm sections were mounted and stained with hematoxylin and eosin.

**Statistical Analysis**

Significance was determined using Students’ t-test with a threshold of 0.05. The sample size used in experiments was a minimum of 5 animals per group per experiment with at least 10 animals used for each parameter tested.

**Results**

**Metalloelastase Is Not Present in the Metalloelastase Gene-Deleted Mice**

To confirm the presence of metalloelastase in the parent strain and its absence in metalloelastase-deficient animals, Western blotting was performed on supernatant from peritoneal macrophages stimulated with LPS and interferon-γ. A 22-kd protein corresponding to the reported molecular weight of fully processed metalloelastase was detected by Western blot using an antibody against the active site of murine metalloelastase in the parent strain wild-type animals. As expected, this band
was absent in metalloelastase-deficient mice, indicating that these mice do not produce functional metalloelastase (data not shown).

**Immune Complex-Induced Lung Injury in Wild-Type and Metalloelastase-Deficient Mice**

Acute lung injury was induced in the mice by IgG immune complexes, and the degree of lung injury was assessed by lung permeability changes, BAL leukocyte counts, and histological evidence of injury. Vascular permeability is a consistent marker of injury in this and several other models of lung injury. After treatment for the prescribed time period, the animals were sacrificed and vascular permeability was assessed in BAL fluid by measuring total protein content. As Figure 1 shows, BAL fluid from uninjured parent strain mice and metalloelastase-deficient mice were similarly low in BAL protein. In contrast, BAL fluid protein levels from injured parent strain wild-type mice showed a marked increase in protein content (1.36 mg/ml) as compared to the saline treated parent strain group. BAL fluid from immune complex-injured metalloelastase gene-deleted mice had a 58% reduction in the quantity of protein (0.58 mg/ml versus 1.36 mg/ml), \( P \leq 0.05 \), in the BAL as compared to the injured wild-type mice. Thus, metalloelastase-deficient mice exhibit lower vascular permeability than the corresponding parent strain mice following formation of immune complexes in the alveolar wall.

**Histological Examination of Injured Lungs**

Histological examination of lungs from wild-type and metalloelastase-deficient mice was performed to qualitatively assess the extent of injury and the infiltration of leukocytes into the alveolar space. As Figure 2 illustrates, lungs from immune complex-injured wild-type animals showed an influx of neutrophils, along with evidence of significant injury with some intracellular hemorrhage and fibrin deposition. In contrast to the injured parent strain mice, lungs from metalloelastase-deficient animals had less injury with a much smaller degree of leukocyte influx, suggesting that the reduced injury in these animals is associated with a reduction of neutrophil recruitment into the alveoli.

**Inflammatory Cell Infiltration into Metalloelastase-Deficient Mouse Lungs**

To further assess the protective effect of metalloelastase deletion, we quantitated the numbers of BAL leukocytes infiltrating the lungs of parent strain and metalloelastase-deficient gene-deleted mice. As Figure 3 shows, both saline treated parent strain and saline treated metalloelastase-deficient mice exhibited minimal neutrophil influx. In contrast, significant neutrophil influx was observed in both parent strain and metalloelastase-deficient gene-deleted mice following immune complex injury, with the influx observed in the metalloelastase-deficient group being ~50% of that of the injured parent strain group \( P < 0.05 \). The metalloelastase-deficient mice exhibited neutrophil counts between that of the saline treated metalloelastase-deficient and the immune complex-treated parent strain mice, which correlated with the vascular...
permeability data. In contrast to the data with neutrophils, there was no significant difference in BAL macrophage counts between saline treated control animals and those that were injured (Figure 3B).

Gelatinase A and Gelatinase B Cannot Compensate for the Absence of Metalloelastase

To assess any compensatory effects of other MMPs in the metalloelastase-deficient animals, we examined gelatinase A and gelatinase B levels in the BAL fluid from control and injured knockout mice. The rationale for the analysis was based on our previous studies and those of others that have shown consistent up-regulation of gelatinase activates in inflammation including acute lung injury. As shown in Figure 4, gelatinase B levels in both saline-treated control and saline-treated, metalloelastase-deficient animals were similarly low. Gelatinase B levels increased significantly following injury (in both control and metalloelastase-deficient animals), and there was a modest increase in gelatinase A. The gelatinase levels in the injured knockout animals were actually slightly lower than that found in the parent strain, suggesting that gelatinase B does not play a compensatory role in the reduced lung injury elaborated in metalloelastase-deficient animals. Similarly, the levels of gelatinase A in the BAL fluid from injured control mice and gene-deleted mice were the same. Thus, neither gelatinase A nor B seem to have the ability to compensate for the lack of metalloelastase in this model of acute alveolitis.

Discussion

MMPs, including metalloelastase, have long been suspected of playing a role in the pathogenesis of tissue injury seen in inflammation including lung injury. However, the lack of selective inhibitors of the MMP activities in vivo has hampered the determination of the phlogistic role of the individual MMPs. Using mice selectively depleted of MMPs, such as metalloelastase or gelatinase B, has allowed for such an analysis. Using mice selectively depleted of metalloelastase, we found in this study that metalloelastase appears to be playing a role in the tissue injury observed in a model of acute lung injury. Previous studies have demonstrated a role for metalloelastase in the pathogenesis of a model of emphysema, but this study is the first to implicate this enzyme in acute lung injury as well.
The source of the metalloelastase in these models appears to be the leukocytes, which correlates with our previous studies showing that neutrophils and macrophages appear to be the primary source of the MMPs up-regulated in lung injury, with metalloelastase from macrophages appearing to be the major source of metalloelastase in the lung emphysema model. In fact, the major elastase activity in the macrophage is metalloelastase, which is up-regulated in cigarette smokers as well as patients with emphysema.

Our previous studies with this acute lung injury model have also identified oxidants as being involved in the initiation of the injury, in part by their up-regulation of the production of inflammatory mediators such as tumor necrosis factor-α, as well as their activation of MMPs, in particular gelatinase B, which is also up-regulated during acute lung injury. Oxidants such as hydrogen peroxide also can upregulate MMP production through activation of AP-1 and oxidants can also directly activate MMP activities. Thus, emerging evidence suggests that MMP production is modulated by other inflammatory mediators and that the up-regulation and activation of MMPs in the lung is ultimately responsible for much of the resulting lung injury.

The mechanism of action of the MMPs in the pathogenesis of tissue injury has been primarily focused on their known ability to break down all types of extracellular matrix. The MMPs are felt to play important roles in the regeneration, wound healing, and inflammation. For example, in patients with asthma or adult respiratory distress syndrome there is an overproduction of MMPs in the lung as compared to levels of the TIMP MMP inhibitors. Experimentally, we have also found that MMP and TIMP levels are both up-regulated in lung injury.

In vitro, decreased neutrophil migration through Matrigel-coated filters has been reported in the presence of MMP inhibitors and the gelatinases in particular have been implicated in the transmigration of eosinophils and lymphocytes. Metalloelastase has also been identified as a requirement for the infiltration of macrophages in a murine model of inflammation with less infiltration of a Matrigel substrate by macrophages from metalloelastase-deficient mice. Studies are ongoing to determine whether metalloelastase or other MMPs such as the gelatinases are required for neutrophil infiltration.

In a third possible mechanism of MMP involvement in lung injury is the modulation of biologically active mediators such as tumor necrosis factor-α and the interleukins. For example, in a model of chronic dermal inflammation, gelatinase B-deficient mice had less injury associated with higher levels of the anti-inflammatory cytokine interleukin-10. Also, MMPs have the ability to shed biologically active molecules such as TNF-α, IL-1, and IL-6 from the surface of macrophages, which, in turn, are known to up-regulate MMP production by both these and parenchymal cells. Thus, it is possible that MMPs, such as metalloelastase, can affect lung injury by altering the levels of pro- and anti-inflammatory cytokines.

In summary, these studies provide evidence that metalloelastase plays a significant role in the pathogenesis of a model of acute lung injury. Extending the observations on the role of metalloelastase in chronic lung injury this study provides additional evidence of an important role for this MMP in lung injury. Furthermore, this study supports the findings in the chronic lung injury model suggesting that metalloelastase plays an important role in leukocyte recruitment into the lung in addition to directly damaging the lung. Dissecting the role that MMPs appear to play in leukocyte recruitment could provide important new information on the mechanisms of this response.
