The role of pancreatic acinar cells in initiating fibrogenic responses during the early stages of alcoholic acute pancreatitis has not been evaluated. We investigated the ability of injured acinar cells to generate pancreatic fibrosis in acute pancreatitis. Rats were fed either an ethanol-containing or control diet over 14 weeks and euthanized 3 or 24 hours after a single lipopolysaccharide injection. Profibrotic transforming growth factor-β of acinar cells and pancreatic fibrosis were assessed by immunofluorescence, histological characteristics, and electron microscopy. Human pancreatic tissues were also evaluated. Periacinar cell fibrosis and collagen were exacerbated 24 hours after endotoxemia in alcohol-fed rats. Alcohol exposure exacerbated acinar cell–specific production of transforming growth factor β in response to lipopolysaccharide in vivo and in acinar cell–like AR42J cells in vitro. Although a morphological examination showed no visible signs of necrosis, early pancreatic fibrosis can be initiated by little or no pancreatic necrosis. Transforming growth factor β was also significantly increased in human acinar cells from patients with acute/recurrent pancreatitis compared with chronic pancreatitis tissue. Alcohol exacerbates lipopolysaccharide-induced pancreatic fibrosis during the early onset of mild, subclinical, acute pancreatitis. We suggest that multiple, subclinical, acute pancreatitis episodes can accumulate in fibrosis during the development of chronic pancreatitis, even if there is no history of acute pancreatitis. (Am J Pathol 2013, 183: 1508–1517; http://dx.doi.org/10.1016/j.ajpath.2013.07.023)

Experimental models of alcoholic pancreatitis have shown that lipopolysaccharide (LPS) exacerbates the development of alcoholic acute pancreatitis (AP) and that exposure to multiple applications of LPS results in fibrogenesis and chronic pancreatitis (CP).1–8 We recently reported that the combination of alcohol and endotoxemia attenuated the apoptosis response, disrupted autophagy signaling, and enhanced pancreatic injury, causing an early onset of AP, which supports clinical observations that episodes of acute and recurrent pancreatitis can progress to CP.2,4 Alcohols seem more susceptible to AP, a condition associated with an earlier onset, more frequent episodes, and an increased risk of CP.5–8 Alcoholic patients also have elevated serum LPS concentrations, which have been associated with the severity of alcoholic AP.9,10

Previously accepted consensus definitions of AP and CP postulate that these two clinical syndromes are independent of one another.11 Episodes of AP in patients with alcoholic CP are thought to be complications of underlying subclinical CP.12 A popular alternate hypothesis is the necrosis-fibrosis sequence model, in which pancreatic fibrosis and CP occur by recurrent episodes of AP with localized pancreatic necrosis.13,14 However, many patients with CP have no history of clinical AP. Because clinical data and tissue specimens are lacking from patients with AP, in particular from subclinical cases, it remains elusive if subclinical AP episodes can accumulate fibrosis during the development of CP.

According to the necrosis-fibrosis hypothesis, the initial event inducing pancreatic fibrogenesis would require either acinar or ductal cell death by necrosis, followed by tissue destruction and fibrosis.5 Thus, pancreatic fibrosis and CP would result from recurrent episodes of AP accompanied by localized pancreatic necrosis.15 In this case, acinar cell
death through necrosis would be required to initiate a strong inflammatory response, followed by immune cell infiltration and the activation of pancreatic stellate cells (PSCs).16–18 Experimental research has shown that activation of PSCs is required to initiate fibrogenesis and CP.17–20 Binding of the profibrogenic transforming growth factor β (TGF-β) activates PSCs, resulting in their proliferation, the production and deposition of collagen 1A1, and pancreatic fibrogenesis.18,21 TGF-β, a multifunctional cytokine and one of the most investigated profibrogenic factors, is elevated in patients with acute necrotizing pancreatitis and participates in pancreatic fibrogenesis.22–27

The role of pancreatic acinar cells in initiating fibrogenic responses during the early stages of AP has not been precisely determined. Because various cell types within the pancreas, including PSCs and the influence of other organs, may modulate TGF-β expression during the course of AP, we have attempted to clarify the origin of TGF-β during the early onset of AP using rat and human samples. We also have analyzed whether acinar cells are the first responders to alcohol and LPS and are able to generate profibrogenic responses in this model of subclinical pancreatitis.

Materials and Methods

Animals and Reagents

Male Sprague-Dawley rats were purchased from Charles River (Sulzfeld, Germany). All experiments were approved by the Institutional Animal Care and Use Committee in accordance with the guidelines of the University of Heidelberg (Heidelberg, Germany) and the Federal Presiding Board of Animal Care (Karlsruhe, Germany).

Antibodies were selected according to proven functionality in formalin-fixed, paraffin-embedded (FFPE) tissue sections by the seller or by publication records. Mouse monoclonal anti-α-smooth muscle actin (SMA; sc-32251) and anti-α-amylase (sc-46657) were purchased from Santa Cruz, Biotech (Heidelberg). Mouse monoclonal anti-collagen 1A1 (ab6308) and rabbit anti-TGF-β (ab66043) were purchased from Abcam (Cambridge, UK). All antibodies were suitable for rat and human samples. Secondary anti-rabbit Cy3 or Cy5-conjugated and anti-mouse Cy5-conjugated antibodies were obtained from Medac GmbH (Wedel, Germany). PCR primers for collagen were purchased from Eurofins MWG Operon (Ebersberg, Germany). All other chemicals were from Sigma-Aldrich (Deisenhofen, Germany), if not stated otherwise.

Experimental Design

Male rats, weighing 150 to 175 g, were fed a commercially available liquid diet, according to Lieber and DeCarli28 (BioServ, Frenchtown, NJ), containing either ethanol (6% final concentration, equivalent to 36% of caloric intake in 15 rats) or maltose-dextrin (pair-fed group in 15 rats) in isocaloric amounts, as described previously.2 After 14 weeks of feeding the control or alcohol diet, Gram-negative bacterial LPS (Escherichia coli, 026-B6; 0.8 mg·kg⁻¹ body weight, i.v.) or vehicle control (sterile saline) was injected once i.v. Rats were divided into six groups each, with five animals per group: pair-fed (PF) (n = 5) and alcohol-fed controls (n = 5), and PF or alcohol-fed animals injected with LPS, sedated at 3 or 24 hours after LPS injection (n = 5) with pentobarbital (Nembutal, 60 mg·kg⁻¹ body weight, i.p.) (Nembutal; Ovation Pharm, Deerfield, IL). The whole pancreas was resected, immersed in liquid nitrogen, and stored at −80°C.

Human Subjects

The study was approved and renewed in August 2012 by the Ethics Committee of the University Medical Faculty of Heidelberg. Human pancreatic tissues were obtained from patients attending the Department of Surgery of our university. In detail, the series comprised three cases of acute pancreatitis (AP)/recurrent acute pancreatitis (RAP), obtained from three men aged 60, 64, and 70 years (average age, 64 years). Alcohol consumption was known in one of these patients. The remaining two patients did not have a reported history of alcohol use, and pancreatitis occurred after low cardiac output syndrome following heart transplantation and for unknown idiopathic reasons in one case each. The CP group consisted of five male and two female patients, aged between 52 and 70 years (average age, 58 years). A history of alcoholism was known in five of these patients; one case represented obstructive pancreatitis due to impn-related pancreatic cancer, and in one patient the CP was idiopathic. The indications for pancreatic head resections were pain- and CP-related complications in organs neighboring the pancreas, such as common bile duct stenosis, main pancreatic duct stenosis, vascular obstruction, and/or duodenal obstruction. Normal human pancreatic tissues were obtained from one female and two male patients (aged 31, 59, and 72 years; average age, 54 years) who were free of pancreatic disease (through an organ donor program in which there were no candidates for pancreatic transplantation).

With one exception, all samples (AP, CP, and controls) were taken from the pancreatic head. One case was taken from the pancreatic tail. Freshly removed tissue samples were immediately fixed in 4% buffered formalin.

To determine the stage of the disease, the fibrosis and severity and activity of the inflammation were microscopically evaluated according to previously described criteria.29 The control samples revealed regular pancreatic tissue, consisting of lobules of acinar cells, ducts, and scattered islets. Focally, mild fibrosis was detected in two cases (scores 0, 1, and 2). There was no significant inflammation (severity score, 0; activity score, 0). In chronic pancreatitis, periductal, interlobular, and intralobular fibrosis was seen to various extents (scores, 4 to 12; average score, 6.9).
Furthermore, the pancreatic tissues displayed mild to moderate chronic inflammation with scattered lymphocytes (severity scores, 1 to 2; average score, 1.4). The activity of the inflammation was mild in three cases (score, 1), mild to moderate in one case (score, 2), and absent (score, 0) in three cases (average score, 0.7). Necrosis was generally lacking. In acute/recurrent pancreatitis, the samples showed multiple areas of fatty necrosis and partially dense infiltrates of neutrophils (activity scores, 2, 3, and 3; average score, 2.7) and lymphocytes (severity scores, 2, 2, and 3; average score, 2.3). Mild to moderate, diffuse interlobular and intralobular fibrosis was seen in one of these cases (score, 9), whereas the remaining two cases presented only scarce, focal fibrosis (scores, 2 and 3).

Immunofluorescence

Immunofluorescence was conducted using pancreatic FFPE tissue sections (5 μm thick) obtained from rat and human specimens and processed as described. Primary antibodies were incubated in antibody diluent (Dako, Hamburg, Germany) for 30 minutes at 37°C in a dark humidified chamber, followed by several steps of washing. Sections were then incubated with anti–mouse-Cy5 and/or anti–rabbit-Cy3 secondary antibodies for 30 minutes at 37°C in the dark, also followed by several steps of washing and incubation with DAPI for 20 minutes. The sections were mounted in Fluoromount-G Reagent (SouthernBiotech, Birmingham, AL). Ten images per slide/sample, with typically 1700 to 3500 cells (63× objective) were captured using a Zeiss Axiosvert 200M microscope (Zeiss, Göttingen, Germany) equipped with DAPI, Cy3, and Cy5 filters (Chroma Technology, Rockingham, VT), as described recently. Brieﬂy, standardized automatic acquisition was performed by AQuest software version 2.2 (TissueGnostics, Vienna, Austria) controlling filters, exposure time, camera (PCO, Kehlheim, Germany), and motor stage (Märzhäuser, Wetzlar, Germany). All images were processed using (TissueGnostics), allowing the quantitation of the total cell numbers from DAPI-positive cells and quantitation of target-positive cells. In ﬂuorescence-activated cell sorter (FACS)–like scattergrams, the cells were plotted according to their Cy3 and Cy5 immunofluorescence (IF) intensity versus their DAPI intensity from 10 randomly captured images. The IF-positive cells were gated in the scattergrams, according to negative controls (no primary antibody), and the fluorescence intensity was expressed as percentage of the intensity of the DAPI staining, as described recently. Likewise, cellular colocalization of rat and human α-amylase with TGF-β was analyzed, and cells were counted in the same way, with the software-supported colocalization analysis.

IHC Data

Immunohistochemistry (IHC) was also conducted using pancreatic FFPE tissue sections (7 μm thick) obtained from rat and human specimens, which were processed using mouse monoclonal anti–α-SMA, as described previously.

In Vitro Alcohol and LPS Stimulation

The rat pancreatic acinar-like AR42J cell line was purchased from ATCC (Manassas, VA), and cells were grown in Ham’s F-12 medium supplemented with 20% heat-inactivated fetal calf serum, 50 U/mL penicillin G, 50 μg/mL streptomycin, and 2.5 mg/mL plasmocin. The cells were maintained at 37°C in a humidified atmosphere of 95% air and 5% CO2. AR42J cells were suspended and plated onto sterile coverslips (Nalgene; ThermoScientific, Waltham, MA) in 6-well tissue culture plates at a density of 300,000 cells per well and incubated for 24 hours. The cells were treated with various doses of ethanol (50 to 400 mmol/L), with or without 10 μg/mL LPS, for another 24 hours. After fixation with 2% paraformaldehyde for 30 minutes in the dark at room temperature, the cells were IF stained for TGF-β and α-amylase, as described. All cells were mounted in Fluoromount-G Reagent, and a minimum of 10 images per treatment were captured and analyzed using the same microscope and software, as described. All in vitro experiments were repeated at least three times.

Pancreatic Histological Characteristics

Pancreata were cut into serial sections (4 μm thick) from 4% FFPE blocks. Sections were stained with H&E and examined by a pathologist (F.B.) who was not aware of the sample identity. Tissue sections (n = 4) were examined for parenchymal edema, acinar cell vacuolization, necrosis, inflammatory cell infiltration, and hemorrhage, and analyzed in 10 randomly selected fields with the aid of the Olympus BX40 microscope camera system (Hamburg, Germany), as described previously.

Electron Microscopy Observation

Frozen pancreatic tissue (n = 4) was fixed in ice-cold 1.5% paraformaldehyde and embedded in Epon 812 (Sigma-Aldrich). Ultrathin sections were prepared for microscopy according to a routine procedure described previously. Briefly, areas within scanned images of electron micrographs were measured using a Metamorph-tracing semi-automatic counting tool. The fibrosis index was determined by an automatic computer-assisted tracing tool in relation to the entire traced area using analySIS 3.2 Software (Soft Imaging System, Munster, Germany) and expressed in mm2 fibrosis in relation to the entire region. All areas were calibrated to scale bars on the micrographs and expressed as a percentage of the entire region measured, and were digitally evaluated in four animals per group (n = 4) in 100 randomly selected 45 × 45-μm fields per animal, as described. Electron microscopic (EM) analysis was performed using an analytical device (EM 902; Zeiss, Oberkochen, Germany).
coupled with a Pro-Scan digital camera (Troendle, Munich, Germany).

Real-Time PCR

Frozen whole pancreatic tissue was powdered in the presence of liquid nitrogen and extracted using TRIzol-Reagent (Life Technologies-Invitrogen, Carlsbad, CA). Total RNA (5 µg) was reverse transcribed using SuperScript II (Life Technologies, Invitrogen), according to the manufacturer’s instructions. A real-time PCR was analyzed on a TaqMan 7000 (Applied Biosystems, Foster City, CA) under standard conditions, using the TaqMan system. The calculated cycles were subtracted from the 18s RNA (Applied Biosystems) reference, which was always included on the same plate. The difference in cycles was then calculated and expressed as previously relative transcript levels (2^DDCt). The TaqMan primer and probe sequences for collagen-3a-1 were designed using ABI primer express software: forward: 5'0-GTGAAAGAGGATCTGAGGGCTC-3'0, reverse: 5'-GAGTTCAGGGTGGCAGATTT-3', and probe: 5'-TGCTGCCATTGCTGGAGTTGGA-3'. Real-time PCR was analyzed as described.30

Statistical Analysis

Statistical analysis was performed by using the analysis of variance, followed by the Student’s t-test for each experimental group treated with LPS or vehicle. Results were considered significant when P < 0.05, and were reported as means ± SEM or as normalization to control samples. Statistical calculations were performed using software from GraphPad Prism 5 (La Jolla, CA).

Results

Pancreatic Fibrosis Is Established at the Early Onset of Subclinical Pancreatitis

We investigated whether LPS induced subclinical pancreatic fibrogenesis in the alcohol-fed animals. We investigated fibrosis by applying electron microscopy and determining the collagen deposition (Figure 1A). EM collagen deposition increased significantly in pair-fed controls (12-fold) and alcohol-fed animals (15-fold), 24 hours after LPS. Alcohol alone increased collagen deposition by 14-fold when compared with pair-fed animals, whereas the combination of alcohol and LPS increased collagen by 1.355-fold compared with LPS alone (Figure 1B). We did not find collagen deposition 3 hours after LPS. We confirmed this surprising result by tissue IF staining for collagen staining (Figure 1C). Collagen level significantly increased by 13-fold in pair-fed controls and by 25-fold in alcohol-fed animals 24 hours after LPS compared with pair-fed controls. Alcohol alone for 14 weeks also increased collagen by threefold, whereas the combination of alcohol and 24-hour LPS increased collagen by 2.3-fold compared with pair-fed controls 24 hours after LPS (Figure 1D). Collagen mRNA expression was confirmed by real-time PCR (Supplemental Figure S1).

IHC is typically used to stain α-SMA, a marker for stellate cells. We also observed elevated α-SMA expression in alcohol-fed animals 24 hours after LPS, indicating more PSCs after alcohol exposure 24 hours after LPS (Figure 1E). In addition, we counted the number of PSCs in the EM samples in a similar manner to determine collagen deposition. In the EM samples, the number of PSCs increased in pair-fed controls by 12-fold and in the alcohol-fed animals by 32-fold 24 hours after LPS, whereas alcohol alone increased PSCs by 20-fold when compared with the PF controls. There was also a 2.5-fold increase in PSC numbers in the alcohol-fed group compared with pair-fed animals 24 hours after LPS (Figure 1F).

Overall, we were able to show exacerbated pancreatic fibrosis as early as 24 hours after LPS in this model of subclinical acute alcoholic pancreatitis.

Alcohol-Enhanced LPS-Induced TGF-β Production in Pancreatic Acinar Cells

We next determined whether TGF-β signaling is altered in the experimental settings because TGF-β is the major regulator for fibrogenesis.13 We investigated the expression of TGF-β and α-amylase using double IF staining (Figure 2A). TGF-β was found in the basolateral region of the acinar cell, whereas α-amylase was found mostly in the apical region, indicating a true distribution within acinar cells (representative shown for TGF-β/α-amylase) (Figure 2B). All results were obtained from FACS-like scattergram analysis (Figure 2C). TGF-β and α-amylase colocalization increased significantly in pair-fed and alcohol-fed animals 24 hours after LPS and was significantly higher in alcohol-fed animals. Almost identical results were obtained for the expression of TGF-β alone. Moreover, α-amylase expression alone showed a significant reduction after alcohol exposure, suggesting alcohol-reduced α-amylase expression (Figure 2D). We confirm our data by counting all evaluated cells in 10 images for TGF-β positivity alone or in colocalization with α-amylase. Only a few α-amylase-negative cells were positive for TGF-β, indicating that most TGF-βs were produced by pancreatic acinar cells in subclinical acute pancreatitis (Table 1).

Pancreatic necrosis is believed to initiate inflammatory responses, fibrogenesis, and pancreatitis, according to the necrosis-fibrosis hypothesis.13 Histopathological alterations showed mild edema and little vacuolization 24 hours after LPS in both groups. We did not identify any visible signs of intense acinar cell necrosis in the tissues from pair-fed or alcohol-fed animals either 3 or 24 hours after LPS administration (Figure 2E). In addition, we confirmed that TGF-β expression was also evident in acinar-like AR42J cells in vitro (Figure 2F), and increased TGF-β and α-amylase colocalization has been significantly found after LPS and...
alcohol concentrations ranging from 200 to 400 mmol/L (Supplemental Figure S2). LPS significantly increased TGF-β and α-amylase colocalization by 3.2-fold, which was enhanced with 250 mmol/L alcohol by 1.8-fold, indicating that alcohol exacerbated LPS-induced TGF-β production in vitro, confirming, in part, the in vivo results (Figure 2G). These results strengthened the evidence that TGF-β is produced in pancreatic acinar cells during the early onset of AP. We conclude that pancreatic acinar cells were capable of producing profibrogenic TGF-β, which, in turn, can activate PSCs, collagen production, and fibrogenesis in the early onset of AP.

Human Acinar Cells Expressing Profibrotic TGF-β in Acute/Recurrent Pancreatitis Specimens

We investigated control tissue from donor patients, patients with CP, and AP/RAP specimens to determine the expression of profibrotic TGF-β in areas of intact acini structure, with representative images shown in the H&E-stained tissue sections (Figure 3A). We next determined TGF-β and α-amylase colocalization by IF in tissue obtained from donor, CP, and RAP patients (Figure 3B). TGF-β and α-amylase colocalization increased substantially in AP/RAP tissue compared with donor controls by sevenfold and 4.5-fold, respectively, compared with CP tissue. Similar results were found for TGF-β alone, suggesting that acinar cells produce most TGF-β. α-Amylase expression decreased by 1.3-fold in CP tissue, although α-amylase did not significantly change in AP/RAP samples compared with controls (Figure 3C). We confirm the data by counting all evaluated cells in 10 images for TGF-β positivity alone or in colocalization with α-amylase. Only a few α-amylase-negative cells were positive for TGF-β, indicating that most TGF-β was produced by pancreatic acinar cells in acute/recurrent pancreatitis (Table 2). All results were obtained from the representative shown FACS-like scattergram analysis graph (Figure 3D).

We determined the degree of fibrosis by IF staining for collagen-1 and α-SMA in the human samples. α-SMA and

Figure 3  TGF-β and fibrosis in acinar cells increase in human acute/recurrent pancreatitis specimens. B: Representative IF images and colocalization of TGF-β (Cy3, green), α-amylase (Cy5, red), and DAPI (blue) in human pancreatic tissue specimens. C: Quantitation of TGF-β (Cy3, green) and α-amylase (Cy5, red) colocalization plotted as means ± SEM for human specimens (n = 3 to 7). *P < 0.05. ****P < 0.0001. D: Representative tissue-FACS scattergram analysis obtained from TGF-β and α-amylase colocalization quantitation in human acute/recurrent pancreatitis samples, stained for DAPI-positive nuclei/cells, α-amylase/DAPI quantitation, TGF-β/DAPI quantitation, and TGF-β and α-amylase colocalization quantitation, shown as yellow cells in gate 1. E: The fibrosis markers, α-SMA (Cy5, red) and collagen-1A (Cy5, red), were highly expressed in both chronic pancreatitis and human acute/recurrent pancreatitis specimens.
collagen-I expressions are known to participate in fibrogenesis and are mainly expressed by activated stellate cells.\textsuperscript{16,18} We chose tissue areas with almost intact acini structures to determine periacinar fibrosis in the human specimens. Periacinar collagen-I and \( \alpha \)-SMA expressions appeared to be similar in AP/RAP and CP tissues, indicating that during the course of AP/RAP, fibrosis has been established, along with the high expression level of TGF-\( \beta \), promoting fibrogenesis in AP/RAP patients (Figure 3E).

We were able to confirm the experimental observation in the clinical specimens and suggest that CP can be established with little acinar cell necrosis, and pancreatic acinar cells are the first responders in driving fibrogenesis by expressing TGF-\( \beta \).

### Discussion

Our findings indicate that rat and human pancreatic acinar cells can produce the most important profibrotic mediator, TGF-\( \beta \), in the early onset of acute pancreatitis. We also found that the expression of TGF-\( \beta \) was highly enhanced in response to LPS in alcohol-fed rats, indicating that chronic alcohol exposure exacerbated the degree of fibrosis in this experimental model of subclinical AP. The expression profile of TGF-\( \beta \) clearly indicates that it is produced during the early response to LPS and found exclusively expressed by acinar cells, because only a few \( \alpha \)-amylase-negative cells were positive for TGF-\( \beta \). In addition, acinar cell–like AR42J cells positive for \( \alpha \)-amylase–producing TGF-\( \beta \) in response to LPS and TGF-\( \beta \) expression were also enhanced by alcohol in vitro, confirming the experimental and human results in vivo. Samples from patients with acute/recurrent pancreatitis showed that acinar cells were responsible for the production of TGF-\( \beta \), indicating that human pancreatic acinar cells are also the major source of profibrotic TGF-\( \beta \) in patients with AP. Thus, acinar cells are the major source of TGF-\( \beta \) after early pancreatic injury and during the early course of subclinical AP, with these responses involving the toll-like receptor-4 signaling pathway in acinar cells.

Human and rat pancreatic acinar cells express toll-like receptor-4, indicating that acinar cells are capable of responding directly to LPS.\textsuperscript{1,2,3,4} Our results are the first to show that pancreatic acinar cells express TGF-\( \beta \), and participate in the initiation of acute pancreatitis-associated early fibrogenesis. Although Vonlaufen et al.\textsuperscript{1} have shown that multiple LPS injections cause enhanced fibrosis in alcoholic-fed rats, this study did not evaluate fibrosis or TGF-\( \beta \) production at the early onset of AP in rats or human specimens. Data suggest that the fibrotic process can be initiated by a subclinical AP event and that acinar cells are the first responders to pancreatic injury, producing profibrogenic TGF-\( \beta \), results observed in both human and rat samples. These results also indicated that the profibrotic TGF-\( \beta \) production by acinar cells seems to be a common mechanism in acute pancreatitis and is not associated primarily by acute alcoholic pancreatitis.

Subsequently, TGF-\( \beta \) activates PSCs and promotes collagen deposition and fibrosis, as described by the necrosis-fibrosis hypothesis.\textsuperscript{5,13} TGF-\( \beta \) colocalized with \( \alpha \)-amylase in pancreatic acinar cells, indicating that these cells produce TGF-\( \beta \) during the early stages of AP. Our results are in agreement with recent findings in transgenic models of CP, showing that elastase-promoter–targeted acinar cells with defective TGF-\( \beta \) signaling prevent pancreatic fibrogenesis, and that the overexpression of Smad6 exacerbates pancreatic fibrogenesis.\textsuperscript{25,26,27} Thus, acinar cells are the major source of TGF-\( \beta \) during the early onset of AP, activating PSCs and, subsequently, pancreatic fibrosis. Although PSCs were also apparently responsive to alcohol and LPS, the findings indicate that PSCs do not play a significant role in the initiation of fibrogenesis during the early onset of AP.

Fibrosis varies in degree and may resolve rapidly during recovery from acute subclinical injury in the experimental model. The persistence of mild injury signals or acinar cell stress may be responsible for more severe fibrosis, as observed in patients with alcoholic CP and in experimental models.\textsuperscript{36} Animal models are critical for evaluating early tissue responses to pancreatic injury, because pancreatic tissue is, in general, not available from humans at these early time points. However, we did confirm periacinar cell fibrosis and increased TGF-\( \beta \)\( /\alpha \)-amylase colocalization in acinar cells only from AP/RAP patients, strengthening our experimental results. The detection of TGF-\( \beta \) expression in intact acini in patients with AP/RAP or CP and in the rat model, in the absence of visible areas of necrotic tissue, indicates that CP can be established by subclinical alcoholic AP. Therefore, clinicians may consider that fibrosis in chronic pancreatitis can develop without a history of clinical acute pancreatitis and that the development of fibrosis can be established by multiple subclinical acute pancreatitis cases.

Acinar cells respond to injury-associated stimuli, such as endotoxin, by producing TGF-\( \beta \). This, in turn, activates PSCs, fibrogenesis, and the infiltration of immune cells, in accordance with clinical findings that CP is often
established without either clinically acute or recurrent episodes of pancreatitis.

Acknowledgments

We thank Drs. David J. Hackam, Ian Deacciuc, and Nathalia Giese for their help; Karin Ruf, Brunhilde Bentzinger, and Peter Rieger for technical assistance; and the Pathophysiology Department at the University of Heidelberg for the immunofluorescence microscopy support.
