*Sarcoidosis* is a systemic granulomatous disease characterized by a variable clinical presentation and course. Although numerous organs may be involved, lungs, lymph nodes, and skin are most commonly affected. However, the cause of sarcoidosis is unknown. Some of the earliest studies on sarcoidosis reported the involvement of *Chlamydia* or *Borreliia*. Recently, sarcoidosis has been reported to be associated with exposure to various microbial agents and environmental substances. Although it has been indicated that mycobacterial infection is related to sarcoidosis because of their clinical and immunopathologic similarities, their association remains controversial.

*Propionibacterium acnes* has been implicated as one of the suggested causative antigens for sarcoidosis, a systemic granulomatous disease. By injecting heat-killed *P. acnes* into the dorsal skin of C57BL/6J mice on days 1, 3, 5, and 14, sarcoid-like granulomatosis was induced in skin and lungs of these mice on day 28. To clarify the role of cell adhesion molecules in cutaneous sarcoidosis, we induced sarcoid-like granulomatosis in mice deficient of intercellular adhesion molecule (ICAM)-1, L-selectin, P-selectin, or E-selectin via repeated *P. acnes* injection. Histopathologic analysis revealed that granuloma formation was aggravated in the skin and lungs of ICAM-1−/− mice compared with wild-type mice. Within skin granulomas of ICAM-1−/− mice, *P. acnes* immunization up-regulated mRNA expression of tumor necrosis factor-α, although it failed to induce IL-10 mRNA expression in contrast to wild-type mice. Infiltration of regulatory T cells into skin granuloma was similar between wild-type mice and ICAM-1−/− mice. *P. acnes* immunization induced IL-10 production by CD4+CD25+Foxp3+ regulatory T cells in lymph nodes of wild-type mice in vivo, which was absent in regulatory T cells of ICAM-1−/− mice. Our results indicate that ICAM-1 is imperative for inducing regulatory T cells to produce IL-10 in vivo, which would prevent granuloma formation. (Am J Pathol 2013, 183: 1731–1739; http://dx.doi.org/10.1016/j.ajpath.2013.08.021)

infection of *P. acnes* in patients with sarcoidosis. Nishi-waki et al observed that an immune response against indigenous *P. acnes* already exists in the healthy lung. They also demonstrated that expansion of the numbers of recirculating *P. acnes*—primed cells, produced by extrapulmonary sensitization, can specifically cause granulomatous changes of the lung, sharing several similarities with pulmonary sarcoidosis, even in the absence of antigen anchoring. In any case, sarcoidosis granuloma involves infiltration of leukocytes, predominantly macrophages.

In general, leukocyte recruitment into inflammatory sites is achieved using constitutive or inducible expression of multiple cell adhesion molecules. L-selectin (CD62L), E-selectin (CD62E), and P-selectin (CD62P) primarily mediate leukocyte capture and rolling on the endothelium. L-selectin is constitutively expressed by most leukocytes. Although P-selectin is rapidly mobilized to the surface of activated endothelium or platelets, E-selectin expression is induced within several hours after activation with inflammatory cytokines. Intercellular adhesion molecule (ICAM)-1 (CD54), a member of the immunoglobulin superfamily, is constitutively expressed not only on endothelial cells but also on fibroblasts and epithelial cells.

It can be up-regulated transcriptionally by several proinflammatory cytokines, such as tumor necrosis factor (TNF)-α, interferon (IFN)-γ, and IL-1. ICAM-1 forms the counter-receptor for the lymphocyte β2-integrins, such as lymphocyte function—associated antigen (LFA)-1. The ICAM-1/LFA-1 interaction predominantly mediates firm adhesion and transmigration of leukocytes at sites of inflammation. In addition to its key role in the context of leukocyte adhesion, locomotion, and migration, ICAM-1/LFA-1 interaction also functions as a co-stimulatory signal for T-cell activation. Even a high density of T-cell receptors—major histocompatibility complex—antigen complex could not compensate for the lack of ICAM-1/LFA-1 interaction for CD4+ T-cell activation.

Although these cell adhesion molecules play important roles in leukocyte transmigration, the way each molecule contributes to cell infiltration is complex. Inhibition or absence of adhesion molecules has been associated with reduction in inflammation and its sequelae, consistent with a central role for leukocytes in promoting inflammation. In contrast, some studies using adhesion molecule—deficient mice have reported exacerbation of leukocyte recruitment and inflammation. In this case, there may be a possibility that the absence of certain key adhesion molecules reduces recruitment of leukocytes that inhibit inflammation, namely, regulatory T cells (Tregs). Moreover, ICAM-1 deficiency or suppression of its function can affect inflammation through impaired activation or differentiation of T cells as a result of a lack of co-stimulatory signaling. Indeed, lack of ICAM-1 on antigen-presenting cells (APCs) leads to poor T-cell activation and proliferation both *in vitro* and *in vivo*, resulting in poor generation of central memory T cells.

In this study, we examined the role of cell adhesion molecules, such as ICAM-1, L-selectin, P-selectin, and E-selectin, in the *P. acnes*—induced sarcoidosis model, using mice deficient in these molecules. Remarkably, in ICAM-1−/− mice, skin and lung granuloma formation was aggravated without showing a defect in Treg infiltration into the skin. Compared with wild-type mice, ICAM-1−/− mice showed reduced IL-10 production by Tregs, indicating the essential role of ICAM-1 in the suppression of skin granuloma formation by Tregs through induction of an anti-inflammatory mediator, IL-10.

### Materials and Methods

#### Mice

L-selectin—deficient (L-selectin−/−) mice were provided by Thomas F. Tedder and were previously described in their article. *ICAM-1−/−*, P-selectin−/−, and E-selectin−/− mice were obtained from The Jackson Laboratory (Bar Harbor, ME). All mice were backcrossed 10 generations onto the C57BL/6 genetic background. Mice used for experiments were 6 to 10 weeks old. Body size and lung size were similar in mutant and wild-type mice (data not shown). All mice were housed in a pathogen-free barrier facility and screened regularly for pathogens. All studies and procedures were approved by the Committee on Animal Experimentation of University of Tokyo.

#### Heat-Killed *P. acnes* Injection

*P. acnes* (ATCC, Manassas, VA) was dissolved in PBS at a concentration of 10⁹/mL and heat-killed at 85°C for 10 minutes. One hundred microliters of heat-killed *P. acnes* or PBS was injected subcutaneously into the shaved back skin of the mice on days 1, 3, 5, and 14 (Supplemental Figure S1).

#### Histopathologic Assessment of Skin and Lung Granulomas

Morphologic characteristics of skin and lung sections were assessed under a light microscope. All skin and lung samples were taken on day 28 after *P. acnes* or PBS injection. Skin samples were obtained from the nodular region on the dorsal skin into which *P. acnes* or PBS had been injected on day 14. Sections were stained with H&E. The skin granulomas were relatively circumscribed. We measured the thickest part of

the granuloma vertical to the epidermis in each section (Supplemental Figure S2). The severity of lung granuloma was semiquantitatively assessed according to a grading scale (Table 1), referring to fibrosis assessment as described previously: the lung granuloma was graded on a scale of 0 to 4 by examining randomly chosen fields of the left middle lobe at a magnification of ×100. Data were obtained from six to eight mice per group. All of the sections were scored independently by two masked investigators.

Immunohistochemical Staining

Paraffinized tissue sections of skin and lung taken from P. acnes— injected mice were deparaffinized and stained with rat anti-mouse F4/80 monoclonal antibodies (Abs; Serotec, Oxford, United Kingdom) or rat anti-mouse Foxp3 monoclonal Abs (eBioscience, San Diego, CA) according to the manufacturer instructions. Foxp3-positive cells in skin were counted in three random grids per mice under magnification of ×400 high-power fields. Data were obtained from six mice per group. Each section was examined independently by 2 masked investigators.

RNA Isolation and Real-Time PCR

Total RNA was isolated from tissue using RNeasy fibrous tissue kit (Qiagen, Crawley, United Kingdom). Granuloma tissue that was confirmed as a nodule macroscopically was obtained for P. acnes— injected skin samples. Total RNA from each sample was reverse-transcribed into cDNA using TaqMan Reverse Transcription Reagents (Invitrogen, from each sample was reverse-transcribed into cDNA using tissue kit (Qiagen, Crawley, United Kingdom). Granuloma P. acnes dles, followed by Flow Cytometry with probes were designed by TaqMan Gene Expression Assays manufacturer instructions. Sequence-specific real-time PCR quantification method according to the manufacturer instructions. Sequence-specific primers and probes were designed by TaqMan Gene Expression Assays (Applied Biosystems). All samples were analyzed in parallel with GAPDH gene expression as an internal control. The relative change in the levels of the genes of interest was determined by the 2^−ΔΔCT method.

Flow Cytometry

A single cell suspension of spleen or lymph nodes was obtained by gentle teasing with forceps and 27-gauge needles, followed by filtering through a nylon mesh. Erythrocytes were lyzed by treatment with ammonium chloride, and the cells were resuspended in BD PharmingenStain Buffer (BD Biosciences, Franklin Lakes, NJ). The cells were first incubated with the respective monoclonal Abs at 1:20 dilution at 4°C for 20 minutes and then with the respective second monoclonal Abs at 1:40 dilution for the next 30 minutes. The final suspension was made in 500 μL of BD PharmingenStain Buffer for analysis. Abs used for analysis via flow cytometry are as follows: APC-conjugated rat anti-mouse CD4 monoclonal Abs (BioLegend, San Diego, CA), phycoerythrin (PE)—conjugated rat anti-mouse CD25 monoclonal Abs (BioLegend), Alexa Fluor 488—conjugated rat anti-mouse Foxp3 monoclonal Abs (BioLegend), PE-Cy7—conjugated rat anti-mouse CD11a Abs (Abcam, Cambridge, MA), and peridinin chlorophyll protein (PerCP)—Cy5.5—conjugated rat anti-mouse IL-10 monoclonal Abs (eBioscience). CD3^+CD25^+Foxp3^+ Tregs in splenocytes were stained using Mouse Treg Flow Kit (BioLegend) according to the manufacturer instructions. Flow cytometry was performed using BD FACSVerse (BD Biosciences).

Intracellular IL-10 Expression Analysis in Tregs in Inguinal Lymph Nodes

Inguinal lymph node cells from P. acnes— or PBS-injected mice were cultured for 2 days in RPMI 1640 complete medium supplemented with 10% (v/v) fetal bovine serum, 2 mmol/L L-glutamine, 100 U/mL of penicillin, and 100 μg/mL of streptomycin at a density of 1 × 10^6 cell/mL (2 mL per well) in a 24-well culture plate, under stimulation of 5 μg/mL of plate-bound anti-mouse CD3 Abs NA/LE (BD Biosciences) and 1 μg/mL of soluble anti-mouse CD28 Abs (BD Biosciences). Cells were fixed, permeabilized, and stained with Abs using a BD Cytofix/CytoPerm Fixation/Permeabilization Kit (BD Biosciences) according to the manufacturer instructions. Briefly, cultured cells were stimulated with a leukocyte activation cocktail and incubated with 2 μL/mL of BD GolgiPlug (BD Biosciences) for 4 hours. Cells were washed and incubated with APC-conjugated anti-mouse CD4 monoclonal Abs and PE-conjugated anti-mouse CD25 monoclonal Abs at 4°C for 20 minutes. Cells were fixed, permeabilized, and then stained with Alexa Fluor 488-conjugated anti-mouse Foxp3 monoclonal Abs and PerCP-Cy5.5—conjugated anti—mouse IL-10 monoclonal Abs or isotype control. These cells were analyzed by BD FACSVerse.

Statistical Analysis

All data are expressed as means ± SD or SEM. Statistical analysis was performed using the Wilcoxon rank sum test for comparison between two groups.

Results

Repeated P. acnes Injection into the Skin Induces Systemic Granulomatosis

We induced systemic granulomatosis by injecting heat-killed P. acnes into the dorsal skin of wild-type mice as described in Materials and Methods. As shown in Figure 1, distinct granulomas were formed in both skin and lungs of mice injected with P. acnes but not in mice injected with PBS. Immunohistochemical analyses revealed that

Role of ICAM-1 in Sarcoidosis

The American Journal of Pathology ■ ajp.amjpathol.org
Acne bacteria, namely P. acnes, seemed to exacerbate granuloma formation in the skin. This was observed in P. acnes-injected wild-type mice, where granuloma formation was thicker compared to PBS-injected wild-type mice. Granulomas in the skin and lungs of P. acnes-injected mice resembled sarcoidosis, with granuloma formation showing thicker granuloma formation. Granuloma formation was assessed histologically using grading scales for skin and lungs. For skin, thickness of granuloma was measured, and for lungs, a grading scale was used for granuloma formation.

Effect of Cell Adhesion Molecules on Granuloma Formation in Skin and Lungs of P. acnes-injected Mice

We next examined the role of cell adhesion molecules in granuloma formation. P. acnes was injected into the dorsal skin of E-selectin-/-, L-selectin-/-, P-selectin-/-, and ICAM-1-/- mice on days 1, 3, 5, and 14. Skin and lung samples were collected on day 28, and histologic sections were made. There were no granulomas in the skin or lungs of PBS-injected mice, whereas granuloma was observed in P. acnes-injected wild-type mice. As shown in Figure 1, granuloma formation in the skin seemed most exacerbated in P. acnes-injected ICAM-1-/- mice compared with other mice, showing thicker granuloma formation. Granuloma formation in the lung seemed to be prominent in E-selectin-/-, L-selectin-/-, and ICAM-1-/- mice compared with the others.

To quantitatively analyze granuloma formation, we performed histologic analyses. For skin, we measured the thickness of the granuloma, and for lungs, we used a grading scale for histopathologic assessment of granuloma formation (Table 1). P. acnes-injected ICAM-1-/- mice presented significantly thicker skin granuloma compared with P. acnes-injected wild-type mice (Figure 2A). For lungs, the granuloma scores were high in P. acnes-injected E-selectin-/-, P. acnes-injected L-selectin-/-, and P. acnes-injected ICAM-1-/- mice compared with P. acnes-injected wild-type mice (Figure 2B). These results demonstrated that granuloma formation was aggravated in both skin and lungs of P. acnes-injected ICAM-1-/- mice compared with P. acnes-injected wild-type mice. Therefore, we focused on examining the role of ICAM-1 in granuloma formation.

Increased TNF-α Expression and Decreased IL-10 Expression in the Skin Granuloma of P. acnes-injected ICAM-1-/- Mice Compared with Wild-Type Mice

We next examined the mRNA levels of TNF-α, IFN-γ, IL-2, IL-4, IL-10, and IL-12 in the skin granuloma on day 28 by quantitative real-time PCR analysis. TNF-α mRNA expression was significantly up-regulated in skin granuloma of P. acnes-injected wild-type mice compared with PBS-injected wild-type mice (Figure 3A). After P. acnes injection, ICAM-1-/- mice exhibited significantly augmented TNF-α mRNA expression relative to wild-type mice. In contrast, although IL-10 mRNA expression was significantly up-regulated in skin granuloma of P. acnes-injected wild-type mice, there was no significant change in IL-10 expression in P. acnes-injected ICAM-1-/- mice compared with wild-type mice.
wild-type mice compared with PBS-injected wild-type mice, IL-10 mRNA expression was not detected in skin granuloma of \textit{P. acnes}–injected ICAM-1\textsuperscript{+/−} mice (Figure 3B). IFN-γ, IL-2, and IL-12 mRNA expressions were hardly detected in the skin of PBS- and \textit{P. acnes}–injected wild-type mice and ICAM-1\textsuperscript{+/−} mice (data not shown). IL-4 mRNA expression was not detected in any of the skin samples (data not shown). These results indicated that exacerbated skin granuloma formation in \textit{P. acnes}–injected ICAM-1\textsuperscript{+/−} mice might be due to increased TNF-α expression and decreased IL-10 expression in the skin granuloma of these mice.

**Comparable Number of Tregs Infiltrating into the Skin Granuloma Between \textit{P. acnes}–Injected Wild-Type Mice and ICAM-1\textsuperscript{+/−} Mice**

Because Tregs are known to be one of the major cell sources of IL-10 during skin inflammation, we first evaluated the number of Foxp3\textsuperscript{+} Tregs infiltrating into the skin granuloma. Cells positively stained with anti-Foxp3 Ab in the skin granuloma were counted in three random grids per mouse under a magnification of ×400 high-power fields (Figure 4A). Skin specimens were isolated from six separate mice, and the mean number was calculated. Although the number of infiltrating Tregs into the skin granuloma of \textit{P. acnes}–injected ICAM-1\textsuperscript{+/−} mice tended to be lower than that in \textit{P. acnes}–injected wild-type mice, the difference was not significant (Figure 4B). Consistent with this, there was no difference in Foxp3 mRNA level in the skin granuloma between these mice (data not shown). Thus, there was no difference in the number of infiltrating Tregs between \textit{P. acnes}–injected ICAM-1\textsuperscript{+/−} mice and \textit{P. acnes}–injected wild-type mice. In the lung, there were only a few Foxp3-positive cells (data not shown), and statistical analysis could not be performed.

**Induced IL-10 Production in Tregs Is Not Detected in ICAM-1\textsuperscript{+/−} Mice Compared with Wild-Type Mice after \textit{P. acnes} Immunization**

Because there was no difference in the number of Tregs infiltrating into skin granuloma between \textit{P. acnes}–injected

---

**Figure 3** Quantitative real-time PCR analysis of TNF-α and IL-10 mRNAs in the skin of wild-type and ICAM-1\textsuperscript{+/−} mice that had been injected with PBS or \textit{P. acnes}. Mice were injected with PBS or \textit{P. acnes}, and total RNA was isolated from skin granuloma on day 28. mRNA levels for TNF-α (A) and IL-10 (B) were determined by quantitative real-time PCR. Data are presented as means ± SD. ND, not detected. **P < 0.01 versus wild-type mice.

Values are presented as means ± SEM. Original magnification: ×600 (A).
ICAM-1<sup>−/−</sup> mice and *P. acnes*–injected wild-type mice, we next examined IL-10 production induced by *P. acnes* immunization in these mice. In these experiments, bulk inguinal lymph node cells were stained with anti-CD4, CD25, and Foxp3 Abs, and CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> cells were determined as Tregs. We first confirmed that CD11a, a component of LFA-1, the ligand for ICAM-1, was expressed on Tregs of ICAM-1<sup>−/−</sup> mice at a level similar to wild-type mice (data not shown). To compare the IL-10 production capacity of ICAM-1<sup>−/−</sup> and wild-type mice in the steady state, inguinal lymph node cells were isolated from PBS-injected ICAM-1<sup>−/−</sup> mice and PBS-injected wild-type mice and cultured overnight with CD3 and CD28 ligation. After culture, intracellular IL-10 expression in Tregs was analyzed by flow cytometry. There was no significant difference in IL-10 production capacity between PBS-injected ICAM-1<sup>−/−</sup> and PBS-injected wild-type mice (Figure 5A).

Next, lymph node cells were isolated from *P. acnes*–injected ICAM-1<sup>−/−</sup> mice and *P. acnes*–injected wild-type mice and cultured overnight with CD3 and CD28 ligation. After culture, intracellular IL-10 expression in Tregs was analyzed by flow cytometry. After *P. acnes* injection, Tregs from wild-type mice produced greater amounts of IL-10 compared with those from ICAM-1<sup>−/−</sup> mice (Figure 5B). In Tregs of wild-type mice, *P. acnes* injection induced IL-10 production compared with PBS injection (Figure 5C). In contrast, there was no such induction observed in Tregs of *P. acnes*–injected ICAM-1<sup>−/−</sup> mice (Figure 5D). Our results indicated that although the IL-10–producing capacity of Tregs was the same between wild-type mice and ICAM-1<sup>−/−</sup> mice in the steady state, *P. acnes*, which induced IL-10 production in Tregs of wild-type mice, failed to induce IL-10 production in Tregs of ICAM-1<sup>−/−</sup> mice.

**Discussion**

In the current study, we induced sarcoid-like granulomatosis in mouse skin and lungs by repeatedly injecting heat-killed *P. acnes* into the skin of wild-type mice. Histopathologic analysis revealed that granuloma formation was aggravated in both skin and lungs of ICAM-1<sup>−/−</sup> mice compared with those of wild-type mice. As for E-selectin<sup>−/−</sup> and L-selectin<sup>−/−</sup> mice, granuloma formation was aggravated only in the lungs. P-selectin deficiency did not have any effect on granuloma formation. *P. acnes* immunization up-regulated TNF-α mRNA expression in skin granulomas of ICAM-1<sup>−/−</sup> mice compared with that of wild-type mice, whereas it failed to induce IL-10 mRNA expression in ICAM-1<sup>−/−</sup> mice. These data suggest that ICAM-1 might play a pivotal role in IL-10 induction during granuloma formation. Because Tregs are known as a major cell source of IL-10, we examined the effect of ICAM-1 on Treg recruitment and function. We did not detect any impairment of Treg recruitment into granuloma of ICAM-1<sup>−/−</sup> mice. However, IL-10 production was induced by *P. acnes* immunization in CD4<sup>+</sup>CD25<sup>+</sup>Foxp3<sup>+</sup> Tregs of wild-type mice but not in the Tregs of ICAM-1<sup>−/−</sup> mice. Thus, our results indicate that...
ICAM-1 is imperative for inducing the production of IL-10 in Tregs during granuloma formation in vivo, using the sarcoidosis mouse model.

The fact that granuloma formation was not confined to the skin injection site led us to consider that the skin granulomas observed in our study were not merely foreign-body granulomas. Nishiwaki et al.\(^\text{15}\) have already made a murine pulmonary sarcoidosis model by injecting heat-killed *P. acnes* into the footpad every 2 weeks for a total of three or four times. In their experiments, immunohistochemical analyses revealed that the CD4\(^++\) T cells in granulomas expressed IFN-γ but not IL-4, which are the Th1 cells,\(^\text{15}\) which is consistent with sarcoidosis.\(^\text{1,15}\) However, there was no verified murine model of cutaneous sarcoidosis yet. We induced skin granuloma that resembled sarcoidosis within 28 days by simply injecting heat-killed *P. acnes* into the mouse dorsal skin four times.

In sarcoidosis, it has been reported that activated CD4\(^++\) cells differentiate into Th1-like cells that secrete predominantly IL-2 and IFN-γ, augment TNF-α production by macrophages, and thereby amplify the local cellular immune response.\(^\text{38}\) Indeed, TNF-α mRNA expression was up-regulated in skin granuloma of *P. acnes*-injected wild-type mice compared with PBS-injected wild-type mice. Furthermore, TNF-α up-regulation was augmented in *P. acnes*-injected ICAM-1\(^+/−\) mice, supporting the histopathologic findings that granuloma formation was aggravated in both skin and lungs of *P. acnes*-injected ICAM-1\(^+/−\) mice compared with *P. acnes*-injected wild-type mice.

Although IL-10 mRNA expression was up-regulated in skin granuloma of *P. acnes*-injected wild-type mice compared with PBS-injected wild-type mice, IL-10 mRNA expression was not detected in skin granuloma of *P. acnes*-injected ICAM-1\(^+/−\) mice. Indeed, several reports indicated increased IL-10 expression in bronchoalveolar lavage fluid of patients with sarcoidosis.\(^\text{39,40}\) IL-10 inhibits the synthesis of various inflammatory cytokines, such as TNF-α, and plays a major role in the regulation of immune responses as an inhibitor of T-cell proliferation and macrophage activation.\(^\text{41−46}\) Therefore, decreased IL-10 mRNA expression could account for the increased TNF-α mRNA expression in skin granuloma of *P. acnes*-injected ICAM-1\(^+/−\) mice. One of the possible cell sources of IL-10 is the Treg, which suppresses T-cell proliferation and inflammation in the skin.\(^\text{47,48}\) Tregs are reported to be increased in patients with active granulomatous sarcoidosis lung.\(^\text{49}\) It has been suggested that despite extensive local inflammation, anergy in active sarcoidosis, as indicated by suppression of the immune response to tuberculin, is accounted for by expansion of Tregs, which abolishes IL-2 production and strongly inhibits T-cell proliferation. Together with our results, these reports led us to study the function of Tregs in ICAM-1\(^+/−\) mice.

LFA-1 (CD11a/CD18) is a component of the receptor for ICAM-1 and is expressed on leukocytes, including Tregs. LFA-1 binds to ICAM-1 expressed on endothelial cells, which enables LFA-1–positive cells to transmigrate into tissues.\(^\text{50−52}\) We first confirmed that absence of ICAM-1 did not affect CD11a expression on Tregs (data not shown). We also confirmed that ICAM-1 deficiency did not affect Treg infiltration into skin granuloma by comparing the number of Foxp3-positive cells and the expression level of Foxp3 mRNA in granuloma because the Foxp3 gene has been identified as the master transcriptional factor of Tregs.\(^\text{53}\) These results suggest that ICAM-1 is not necessary for Tregs to infiltrate into the skin granuloma. This finding was consistent with the previous report that E- and P-selectin ligands expressed on Tregs are adhesion molecules necessary for their infiltration into the skin.\(^\text{54}\) Using a contact sensitivity model, Deane et al.\(^\text{55}\) previously reported that endogenous Tregs adhered in inflamed dermal vessels via ICAM-1 were able to control adhesion of other proinflammatory leukocytes in vivo. Different from their observation within acute inflammation, Treg infiltration was not impaired in our chronic inflammatory sarcoidosis model using ICAM-1\(^+/−\) mice. However, it is still possible that during the acute phase of granuloma formation, there might have been a difference in Treg infiltration.

Sarcoidosis represents an unresolved immunologic paradox: affected organs are the staging ground for an intense immune response, yet at the same time, a state of anergy is established as indicated by suppression of immune response to tuberculin in sarcoidosis patients. Regarding this paradox, it was previously found that although Tregs accumulating at the periphery of sarcoid granuloma and in the peripheral blood exhibit powerful antiproliferative activity that may account for the state of anergy, these Tregs do not completely inhibit TNF-α production.\(^\text{56}\) Thus, our result indicates that ICAM-1 expression might be involved in the insufficiency of Tregs to control local inflammation in sarcoidosis.

In our study, the capacity of Tregs to produce IL-10 in the steady state was comparable between wild-type and ICAM-1\(^+/−\) mice. However, when these mice were immunized with *P. acnes*, although IL-10 production was induced in Tregs of wild-type mice, IL-10 production was not induced in Tregs of ICAM-1\(^+/−\) mice. Consistent with our result, Tran et al.\(^\text{57}\) previously found that interaction between LFA-1 on Tregs and ICAM-1 on dendritic cells is critical for the suppressor function of Tregs. They first demonstrated that suppression of T-cell activation across species is highly efficient in vitro and is cell contact dependent. Then, by using responder CD4\(^++\) T cells from ICAM-1\(^+/−\) mice, they demonstrated that human LFA-1 on Tregs specifically interacts with ICAM-1 on mouse dendritic cells rather than on the responder T cells and that this interaction is sufficient for suppression of T cell activation in vitro.\(^\text{57}\) Our study found, for the first time, that ICAM-1 is imperative for inducing Tregs to produce IL-10 in vivo, which would prevent chronic granuloma formation.
