We investigated the effect of restriction of food intake, a potent inducer of autophagy, on post-infarction cardiac remodeling and dysfunction. Myocardial infarction was induced in mice by left coronary artery ligation. At 1 week after infarction, mice were randomly divided into four groups: the control group was fed ad libitum (100%); the food restriction (FR) groups were fed 80%, 60%, or 40% of the mean amount of food consumed by the control mice. After 2 weeks on the respective diets, left ventricular dilatation and hypofunction were apparent in the control group, but both parameters were significantly mitigated in the FR groups, with the 60% FR group showing the strongest therapeutic effect. Cardiomyocyte autophagy was strongly activated in the FR groups, as indicated by up-regulation of microtubule-associated protein 1 light chain 3-II, autophagosome formation, and myocardial ATP content. Chloroquine, an autophagy inhibitor, completely canceled the therapeutic effect of FR. This negative effect was associated with reduced activation of AMP-activated protein kinase and of ULK1 (a homolog of yeast Atg1), both of which were enhanced in hearts from the FR group.

In vitro, the AMP-activated protein kinase inhibitor compound C suppressed glucose depletion induced autophagy in cardiomyocytes, but did not influence activity of chloroquine. Our findings imply that a dietary protocol with FR could be a preventive strategy against postinfarction heart failure. (Am J Pathol 2014, 184: 1384–1394; http://dx.doi.org/10.1016/j.amjpath.2014.01.011)
is also a mode of cell death that occurs during tissue and organ development to eliminate unnecessary cells. In the heart, autophagy has been shown to be an adaptive response that protects the myocardium from hemodynamic overload and acute ischemic death. Autophagy occurs constitutively within the normal myocardium, but it is substantially increased in cases of ischemic cardiomyopathy, heart failure, and cardiac hypertrophy. The functional role of autophagy in heart disease (ie, whether it mediates cell survival or cell death) and whether it up-regulates or down-regulates cellular function remain poorly understood.

Using a mouse model of myocardial infarction, we recently observed activated autophagy in surviving cardiomyocytes during both subacute and chronic stages of a large myocardial infarction (ie, 1 and 3 weeks after infarction, respectively). In addition, we have found that, although inhibiting this autophagy exacerbates postinfarction cardiac remodeling, enhancing it mitigates the remodeling. We had previously used rapamycin to accelerate autophagy, but administration of rapamycin for long periods could be harmful if applied clinically, because of its inhibitory effect on cell growth. Starvation, on the other hand, is also a potent inducer of cardiac autophagy, and inhibition of starvation-induced autophagy causes heart failure in adult mice. Caloric restriction was reported to stimulate autophagy to mediate some beneficial effects in the heart. We therefore hypothesized that regulated restriction of food intake might augment autophagy to exert beneficial effects on postinfarction cardiac remodeling and dysfunction. In the present study, we restricted food intake to various degrees in mice after large myocardial infarctions and examined both the therapeutic effects and possible pathogenic effects.

**Materials and Methods**

**Animals and Experimental Protocols**

This study conforms to the Guide for the Care and Use of Laboratory Animals published by the NIH (publication 85-23, revised 1996) and was approved by the Institutional Animal Research Committee of Gifu University. Mice were initially anesthetized using 2% halothane in a mixture of N2O and O2 (each at 0.5 L/minute) administered via a nasal mask. The mice were then intubated with a 20-gauge intravenous catheter and ventilated with 0.5% halothane in a mixture of N2O (0.1 L/minute) and O2 (0.5 L/minute) using a rodent ventilator. Myocardial infarction was induced in male C57BL/6J mice (CLEA Japan, Fuji, Japan) at 10 weeks of age by ligating the left coronary artery, as described previously. Sham-treated animals underwent the same surgical procedures except that the left coronary artery was not occluded.

Echocardiographic examination was performed on surviving mice at 1 week after coronary artery ligation (n = 29). Randomly selected mice (n = 6) were allowed free access to food (control group), and the average caloric intake was calculated from the daily food intake over a 2-week period. This was regarded as 100% caloric intake. The remaining mice were assigned to food restriction (FR) groups with food intake at 80% (n = 6), 60% (n = 8), or 40% (n = 9) of the average caloric intake for 2 weeks.

In another set of experiments, mice surviving at 1 week after coronary artery ligation (n = 24) were assigned, after echocardiographic examination, to saline treatment (control) (n = 12) or to treatment with 10 mg/kg chloroquine (Sigma-Aldrich, St. Louis, MO) (n = 12). Treatments were administered for 2 weeks using subcutaneously embedded osmotic minipumps (ALZET micro-osmotic pump 1002; DURECT, Cupertino, CA). Chloroquine is thought to suppress inflammation by raising lysosomal pH, thereby inhibiting lysosomal activity. The 10 mg/kg dose of chloroquine is reported to suppress autophagy in the mouse heart without any apparent adverse effects. To assess the effects of these treatments in mice without infarction, the saline or chloroquine was administered in the same manner to sham-operated mice at 1 week after surgery (n = 3 per group), and all mice were examined at 2 weeks after the start of treatment (ie, 3 weeks after surgery).

**Physiological Studies**

Echocardiography and cardiac catheterization were performed as described previously. Because of its invasiveness, cardiac catheterization was performed only just before sacrifice.

**Histology**

Once the physiological measurements were complete, the mice were sacrificed. The hearts were removed, weighed, and cut into transverse slices at the mid-papillary muscle level. They were then fixed in 10% buffered formalin, embedded in paraffin, cut into 4-μm-thick sections and stained with H&E and Masson's trichrome. Cardiomyocyte size, expressed as the transverse diameter of myocytes cut at the level of the nucleus, was assessed in 20 randomly chosen high-power fields (HPFs) (×600) in each section.

**Immunohistochemistry**

After deparaffinization, 4-μm-thick sections were incubated with a primary antibody against microtubule-associated protein-1 light chain 3 (LC3; MBL Medical & Biological Laboratories, Nagoya, Japan). A Vectastain Elite ABC kit (Vector Laboratories, Burlingame, CA) was then used to immunostain the sections; diaminobenzidine served as the chromogen, and rabbit protein-1 light chain 3 (LC3; MBL Medical & Biological Laboratories, Nagoya, Japan). A Vectastain Elite ABC kit (Vector Laboratories, Burlingame, CA) was then used to immunostain the sections; diaminobenzidine served as the chromogen, and Masson's trichrome. Cardiomyocyte size, expressed as the transverse diameter of myocytes cut at the level of the nucleus, was assessed in 20 randomly chosen high-power fields (HPFs) (×600) in each section. Quantitative assessments, including the number of immunopositive cells or immunopositive dots within cells, were performed in 20 randomly selected HPFs (×600) using a multipurpose color image processor (Nireco, Tokyo, Japan). The border area was defined as the area within a HPF that contains both infarcted...
and surviving myocardium, and the remote area was defined as the myocardial region without any infarction.

**Electron Microscopy**

Cardiac tissue was quickly cut into 1-mm cubes, immersion-fixed in 2.5% glutaraldehyde in 0.1 mol/L PBS (pH 7.4) overnight at 4°C, and postfixed in 1% buffered osmium tetroxide. The specimens were then conventionally processed and examined under an electron microscope (H-800; Hitachi, Tokyo, Japan).

**Western Blotting**

Proteins (20 μg) extracted from hearts (n = 3 to 6 hearts per group) were subjected to 10% or 15% PAGE and then were transferred onto polyvinylidene difluoride membranes. The membranes were probed using the following primary antibodies: LC3 and p62 (MBL); cathepsin D (Santa Cruz Biotechnology, Dallas, TX); AMP-activated protein kinase (AMPK) and phosphorylated AMPK (p-AMPK) (Cell Signaling Technology, Danvers, MA); ULK1 (sc-10900; Santa Cruz Biotechnology) and p-ULK1 (6888; Cell Signaling Technology, Danvers, MA); AMP-activated protein kinase (AMPK) and phosphorylated AMPK (p-AMPK) (Cell Signaling Technology, Danvers, TX); Sirt1 (Millipore, Billerica, MA), and histone H3 and acetylated histone H3 (Calbiochem; Millipore). Blots were then visualized using enhanced chemiluminescence (Amersham; GE Healthcare, Little Chalfont, UK). α-Tubulin (analyzed using an antibody from Santa Cruz Biotechnology) served as the loading control.

**Myocardial ATP Content**

Myocardial ATP content was measured using an ATP bioluminescence assay kit (TOYO Ink Group, Tokyo, Japan) according to the manufacturer’s instructions. Absorbance was measured using a GloMax 20/20n luminometer (Promega, Madison, WI). Experiments were performed in triplicate for each group.

**In Vitro Study**

Cardiomyocytes were isolated from 1-day-old neonatal C57BL/6J mice as previously reported. Cardiomyocytes were then plated in laminin-coated slide glass chambers and incubated in Dulbecco’s modified Eagle’s medium (Sigma-Aldrich) containing 10% fetal bovine serum (Sigma-Aldrich) and penicillin/streptomycin at 37°C in a CO2 incubator (95% air/5% CO2). At 2 days after plating, the medium was replaced with fetal bovine serum–free Dulbecco’s modified Eagle’s medium (control group), or with fetal bovine serum–free and glucose-free Dulbecco’s modified Eagle’s medium (Gibco 0983; Life Technologies, Carlsbad, CA) in which glucose was replaced with 11 mmol/L mannitol (starvation group), or with fetal bovine serum–free Dulbecco’s modified Eagle’s medium containing 3 μmol/L chloroquine for 4 hours (chloroquine-treated group). Each group was then treated with vehicle or 20 μmol/L of the AMPK inhibitor compound C (Calbiochem; Millipore). Four hours later, cells were subjected to Western blotting for AMPK, p-AMPK, ULK1, p-ULK1, and β-actin (Sigma-Aldrich), or to immunofluorescence assay for LC3 using anti-LC3 antibody as the primary antibody followed by Alexa Fluor 488 (green; Life Technologies) labeling and Hoechst 33342 counterstain analyzed under a fluorescence microscope (BZ-8000; Keyence, Osaka, Japan), or to measurement of ATP content. Experiments were performed in triplicate for each group.

**Statistical Analysis**

Significance of differences between groups was evaluated using one-way analysis of variance with a post hoc Newman–Keuls multiple comparisons test. P < 0.05 was considered significant. Data are expressed as means ± SEM.

Results

Food Restriction

When fed ad libitum (100%), the mice consumed 3.44 ± 0.5 g food per day during week 1 after myocardial infarction, 3.70 ± 0.6 g during week 2, and 3.74 ± 0.3 g during week 3 (n = 3). Food restriction was started at 1 week after infarction. Thus, the mice receiving 80%, 60%, and 40% of the food consumed by the control group (80% FR, 60% FR, and 40% FR groups, respectively) were fed 3.0 g/day, 2.2 g/day, or 1.5 g/day, respectively, during weeks 2 and 3 after infarction (Table 1).

Effect of FR on Postinfarction Cardiac Function and Remodeling

Echocardiography and cardiac catheterization performed at 3 weeks after infarction revealed marked left ventricular remodeling and dysfunction in the control group, compared with the sham-surgery group (Figure 1). However, these adverse effects were mitigated in the FR groups, with the 60% FR group showing the maximal benefit (Figure 1). Histological sections showed that cavity dilatation was diminished in the FR groups (Figure 2A), and although body weights declined in proportion to the degree of FR, the heart weight/body weight ratios were nonetheless smallest in the 60% FR group and were smaller in the all FR groups than in the control group (Table 1). The size of the myocardial infarct (based on the percent segmental length) was also smaller in the FR groups and smallest in the 60% FR group (Figure 2). In the FR groups, cardiomyocyte hypertrophy (based on the mean diameter of cardiomyocytes) was attenuated in the border areas and in areas remote from the infarct, and this tendency was most conspicuous in the 60% FR group (Figure 2B).

Figure 1  Effects of FR on cardiac remodeling and function evaluated using echocardiography and cardiac catheterization at 3 weeks after infarction. A: Representative M-mode echocardiograms at the level of the ventricles in each group. B: Hemodynamic parameters. Data are expressed as means ± SEM. n = 6 mice per group. *P < 0.05 versus sham surgery. †P < 0.05 versus control. ‡P < 0.05 versus 60% FR. bpm, beats per minute; Cont, control; Cq or q, chloroquine; dP/dt, change in pressure over time in the left ventricle; %FS, percent fractional shortening; HR, heart rate; LVEDd, left ventricular end-diastolic dimension; LVSP, left ventricular systolic pressure; MI, myocardial infarction; S, sham surgery; 40 or 60 or 80, FR percentage.
Effect of FR on Autophagy in Postinfarction Hearts

Immunohistochemistry revealed that the numbers of LC3-positive autophagic vacuoles were significantly increased within surviving cardiomyocytes after infarction (Figure 3A). Immunopositive dots were distributed in cardiomyocytes situated both in areas bordering the infarction and in more remote areas. Within the infarct area, however, the dot number was extremely low. In hearts from mice undergoing FR, immunopositive dot numbers were significantly higher than control in both border and remote areas, and the magnitude of the increase was greater in the 40% and 60% FR groups than in the 80% FR group (Figure 3A).

Western blot analysis showed that expression of LC3-II was up-regulated in the postinfarction heart (Figure 3B). The LC3-II/LC3-I ratio was significantly increased, and was increased still further by FR, which is indicative of greater autophagic turnover.29 Cathepsin D, a lysosomal enzyme, was also up-regulated in postinfarction hearts, and this up-regulation was also augmented by FR (Figure 3B). The LC3-binding protein p62 regulates the formation of protein aggregates and is removed in the final digestion step during autophagy.30 Consequently, an increase in p62 levels indicates an increase in protein aggregation or impairment of their digestion. Levels of p62 were significantly increased in the postinfarction heart, but were reduced by FR (Figure 3B).

Electron microscopic examination revealed that both autophagic vacuoles and lysosomes were abundant within cardiomyocytes in the postinfarction heart, and their numbers appeared to be further increased by FR (Figure 4). In addition, direct measurements revealed significantly increased myocardial ATP content in all FR groups, with the highest levels in the 60% FR group (Figure 5). These results suggest that, through energy recycling, autophagy gives full play to cardiomyocyte function in mice undergoing FR.

Effect of Autophagy Inhibition on the Benefits of FR in Postinfarction Hearts

We next investigated effects of inhibiting autophagy using chloroquine on the beneficial effects of FR on postinfarction hearts. We also investigated several autophagy-related signals in this set of experiments. Treatment with chloroquine was started at 1 week after infarction and continued for 2 weeks in the control and the 60% FR groups.
Cardiac Function and Pathology
Chloroquine treatment exacerbated postinfarction cardiac dysfunction and remodeling in both the control and the 60% FR groups; in the latter, chloroquine appeared to cancel the benefits of a restricted diet (Figures 1 and 2).

Cardiac Autophagy
The increase in LC3 immunopositive dots normally seen in cardiomyocytes from mice in the 60% FR group was diminished by treatment with chloroquine (Figure 3A). Expression of both LC3-II and LC3-I was down-regulated in chloroquine-treated hearts, and thus the LC3-II/LC3-I ratio was significantly reduced (Figure 3B). The level of cathepsin D was also markedly reduced by chloroquine (Figure 3B), and the postinfarction reduction in p62 induced by FR was inhibited by chloroquine (Figure 3B). Ultrastructurally, the surviving cardiomyocytes in the chloroquine-treated hearts lacked indicators of autophagic activation, such as abundant lysosomes and autophagosomes (Figure 4). Chloroquine treatment also reduced postinfarction myocardial ATP in control hearts (Figure 5) and significantly attenuated the increase in myocardial ATP normally induced by 60% FR.

Autophagy-Related Signals
We next examined autophagy-related signal transduction in postinfarction hearts with or without 60% FR and/or chloroquine interventions. AMPK belongs to a conserved

Figure 3 Postinfarction accumulation of autophagic vacuoles. A: Immunohistochemical labeling of LC3 (brown) in ventricular tissues in an area remote from the infarct, in tissue bordering the infarct, and within the infarct area. For the remote area, the LC3 immunopositive dots can be seen clearly in the high-magnification images, which correspond to the boxed regions in the adjacent low-magnification image. LC3 immunopositive dots per HPF (×600) were quantified in the remote, border, and infarct areas. B: Western blots of the autophagy-related proteins LC3, cathepsin D, and p62 in heart. The LC3-II/LC3-I ratios were calculated and the intensity of the cathepsin D and p62 bands were quantified. Data are expressed as means ± SEM. n = 6 mice per group. *P < 0.05 versus sham surgery. †P < 0.05 versus control. ‡P < 0.05 versus 60% FR. Scale bar = 20 μm.
family of protein kinases that are activated by ATP depletion and the resultant accumulation of AMP, and it is an important regulator of autophagy stimulated by cellular starvation. A significant increase in the level of activated (phosphorylated) AMPK was observed in the postinfarction heart, and the level was increased still further by 60% FR or chloroquine (Figure 6A). A recent study found that direct activation (phosphorylation) of the mammalian autophagy-initiating kinase ULK1, a homolog of yeast Atg1, is necessary for autophagy induction. As expected, ULK1 activation (based on the myocardial levels of p-ULK1) was significantly increased by FR (Figure 6A).

We also assessed the postinfarction activity of Akt, a key prosurvival molecule that negatively regulates myocardial AMPK activity. Western blot analysis showed that levels of p-Akt were significantly higher in postinfarction hearts than in sham-operated hearts, but they were unaffected by any of the treatments in this study (Figure 6B). This suggests that, in the present model, FR acts directly or indirectly on AMPK without affecting the Akt pathway.

Sirt1 (a NAD<sup>+</sup>-dependent protein deacetylase and a mammalian ortholog of yeast Sir2) deacetylates histone polypeptides, with a preference for histone H3 lysine 9. Sirt1 levels were similar in all of the treatment groups (Figure 6C). On the other hand, the level of acetyl-histone, which is inversely related to Sirt1 activity, was significantly increased in the infarcted heart. The increase in acetyl-histone (reflecting inactivity of Sirt1) was reversed by FR but was unaffected by chloroquine (Figure 6C). Myocardial Sirt1 thus appears to be activated by FR in the infarcted heart, but the lack of effect of chloroquine suggests that Sirt1 is not involved in the autophagic response.

Autophagy-Related Signal Transduction in Cultured Cardiomyocytes

Last, we used cultured cardiomyocytes to investigate the roles played by AMPK and ULK1 in the mechanism underlying FR-induced autophagy. Isolated neonatal mouse cardiomyocytes were treated with glucose-free medium or chloroquine with or without simultaneous treatment with the AMPK inhibitor compound C for 4 hours. Glucose depletion brought about an increase in p-AMPK and p-ULK1 levels and an increase in the numbers of LC3 immunopositive dots (indicating autophagosomes and autolysosomes) observed within cardiomyocytes, but treatment with compound C completely canceled those effects (Figure 7, A and B). The ATP content in cardiomyocytes was increased by glucose depletion, and this increase was inhibited by compound C (Figure 7C). Treatment with chloroquine also led to an increase in p-AMPK and p-ULK1 levels, and an increase in LC3 immunopositive dots, but a marked reduction in the ATP content of cardiomyocytes, none of which were affected by simultaneous treatment with compound C (Figure 7, A–C). Taken together, these results indicate that glucose depletion enhances autophagy via an AMPK–ULK1 pathway, and that glucose depletion and chloroquine regulate AMPK activity and downstream events in distinctly different ways, although both activate AMPK. We suggest that glucose depletion directly activates AMPK to promote autophagy, because autophagy evoked by glucose depletion is inhibited by the AMPK inhibitor. Chloroquine likely inhibits autophagy by interfering with fusion between autophagosomes and lysosomes, which results in a reduction in cellular ATP content and in turn stimulates AMPK activity (Figure 7D).

Discussion

Mechanisms for the Benefits of FR on the Postinfarction Heart

The main finding of the present study is that restriction of food intake after a large myocardial infarction, starting during the subacute stage, significantly mitigates the adverse
left ventricular remodeling and subsequent heart failure seen at the chronic stage. The therapeutic efficiency was strongest in mice receiving 60% of their normal food intake. We suggest that these beneficial effects of FR mainly reflect the ability of the heart to increase autophagic activity, because the autophagy inhibitor chloroquine produced opposite outcomes when administered alone and offset the effects of FR when administered under those conditions. In addition, autophagic activity, myocardial ATP content, and the degree of improvement in left ventricular remodeling and function all varied in parallel with the extent of FR up to 60%, supporting the notion that increases in autophagy induced by FR accelerate energy recycling to the benefit of postinfarction processes in the heart. At 40%, however, FR failed to improve postinfarction left ventricular function and remodeling, despite marked up-regulation of autophagy. In this extreme case, myocardial ATP content was paradoxically reduced. Apparently, even marked up-regulation of autophagy could not compensate for the lack of ATP if FR was too severe to supply sufficient energy.

The accumulation of autophagic vacuoles can represent either increased formation or impaired digestion. In the present study, we confirmed an increase in the LC3-II/LC3-I ratio, which is an established indicator of autophagic turnover.29 Moreover, to examine autophagic flux in vivo, we used chloroquine alone and in combination with FR. Chloroquine inhibits autophagosome–lysosome fusion, thereby preventing the final digestion step in autophagy, and it is frequently used as an autophagy inhibitor.25 In postinfarction hearts, chloroquine suppressed autophagic activity and reduced numbers of autophagic vacuoles and LC3-II/LC3-I ratios, both of which were augmented by FR. These findings indicate that FR increases autophagic turnover or flux in failing hearts with old myocardial infarctions.

We recently studied the time course of autophagy in surviving cardiomyocytes during the 3 weeks after myocardial infarction and found that autophagy was very actively induced in remote areas and in border areas in the myocardium, and that activity in the remote areas was stronger during more chronic stages (2 and 3 weeks after infarction).15 The present study confirmed strong autophagic activity in remote areas at 3 weeks after infarction. With progression of cardiac remodeling, wall stress increases in parallel with ventricular dilatation, in accordance with Laplace’s law. This causes tissue hypoxia, even in the remote myocardium, which may contribute to the induction of autophagy in failing hearts with large old infarctions.

**Autophagy-Related Molecular Signals Evoked by FR**

Energy recycling is one of the most important functions of autophagy, and we previously reported that autophagy increases myocardial ATP levels, leading to improved cardiac performance and cardiomyocyte survival.19 AMPK belongs to a conserved family of protein kinases and serves as a general integrator of the metabolic response to changes in energy availability; it is activated by ATP depletion and concomitant AMP accumulation (increases in the AMP/ATP ratio).31,35 Here, we observed that more strict FR induced higher levels of AMPK activity. We also observed
up-regulation of p-AMPK in chloroquine-treated hearts, which is consistent with our earlier finding that inhibition of autophagy by bafilomycin A1 interferes with the supply of ATP to the ischemic myocardium, leading to AMPK activation.15 The present in vitro experiments suggest that both glucose depletion and chloroquine stimulate AMPK activation. Glucose depletion directly activates AMPK to promote autophagy, whereas chloroquine acts indirectly. By inhibiting autophagy (most likely by interfering with the fusion between autophagosomes and lysosomes23–25), chloroquine reduces ATP levels, which in turn stimulates AMPK activity (Figure 7D). This is reminiscent of previously reported mechanisms regarding the beneficial effect of resveratrol on postinfarction cardiac remodeling.36

It is thought that AMPK can trigger autophagy through an indirect mechanism whereby it inhibits the activity of mTOR complex 1 by phosphorylating tuberous sclerosis type 2 (TSC2) and regulatory-associated protein of mTOR (Raptor).31,37 However, recent findings suggest a more direct mechanism whereby AMPK regulates autophagy through phosphorylation of ULK1 (mammalian homolog of yeast Atg1).38,39 The ULK1 kinase complex plays a central role in the induction of autophagy by regulating the earliest step in autophagosome formation. In the present study, we observed increases in the levels of both p-AMPK and p-ULK1 in the postinfarction heart, which were further increased by FR. This suggests that AMPK activation and subsequent ULK1 activation represent one possible pathway to improved autophagic flux through FR (Figure 7D).

Although we confirmed that FR activates Sirt1, it remains unclear whether Sirt1 has a direct effect on autophagy. Sirt1 activity was maintained in the postinfarction heart despite treatment with chloroquine (Figure 6C). That chloroquine exacerbated left ventricular remodeling and dysfunction without affecting Sirt1 activity implies a dissociation between Sirt1 activity and cardioprotection. Nadtochiy et al40 reported that overexpression of Sirt1 protected against ischemia–reperfusion injury through stimulation of autophagy, but Kawashima et al41 reported that constitutive Sirt1 overexpression impaired mitochondrial function and reduced autophagy, resulting in cardiac dysfunction. Further study would be required to define the role of Sirt1 in postinfarction cardiac remodeling.

Conclusions and Clinical Implications

Food restriction enhances cardiomyocyte autophagy and appears to mitigate postinfarction cardiac remodeling and dysfunction. In mice, the optimal caloric restriction is to...
60% of control. The clinical implication is that a dietary protocol started during the subacute stage of myocardial infarction could be a preventive strategy against progression of postinfarction left ventricular remodeling and heart failure.
