Valproic acid (VPA) is widely prescribed for treatment of epilepsy, mood disorders, migraines, and neuropathic pain. It exerts its therapeutic benefits through multiple mechanisms, including enhancement of GABAergic activity, activation of prosurvival protein kinases, and inhibition of histone deacetylase. Increasing evidence suggests that VPA possesses neuroprotective properties. We examined neuroprotective effects of VPA in an N-methyl-D-aspartate (NMDA) excitotoxicity model, which mimics some of the pathological features of glaucoma. In vivo retinal imaging using optical coherence tomography revealed that NMDA-induced retinal degeneration was suppressed in the VPA-treated retina, and histological analyses confirmed that VPA reduced retinal ganglion cell death. In vivo electrophysiological analyses demonstrated that visual impairment was prevented in the VPA-treated retina, clearly establishing both histological and functional effects of VPA. Brain-derived neurotrophic factor (BDNF) expression was up-regulated in Müller glial cells, and neuroprotective effects of VPA on retinal ganglion cells were significantly reduced in a conditional knockout mouse strain with deletion of tropomyosin receptor kinase B (TrkB), a receptor for BDNF from retinal ganglion cells. The results show that VPA stimulates BDNF up-regulation in Müller glial cells and provides direct evidence that neuronal TrkB is important in VPA-mediated neuroprotection. Also, VPA suppresses oxidative stress induced by NMDA in the retina. Our findings raise intriguing possibilities that the widely prescribed drug VPA may be useful for treatment of glaucoma. (Am J Pathol 2015, 185: 756—764; http://dx.doi.org/10.1016/j.ajpath.2014.11.005)

Valproic acid (VPA), a short-chain fatty acid, is widely prescribed as an antiepileptic drug. The pharmacological action of VPA in the treatment of epilepsy involves multiple mechanisms, including those associated with regulation of GABAergic neurotransmission, which has been studied since the 1970s.1 VPA is also used for treatment of mood disorders, migraines, and neuropathic pain,2-4 which indicates both tolerance and clinical importance. The diversity of uses may be explained by the fact that VPA affects numerous systems. Multiple intracellular signal transduction pathways are modulated by VPA, as a result of its action on regulation of enzymatic activities including phosphatidylinositol 3-kinase/Akt-1, mitogen-activated protein kinases and glycogen synthase kinase 3β, and histone deacetylase.5-7 There is increasing evidence that VPA has neuroprotective properties, and in recent studies VPA has shown promising results in several models of acute injury (including stroke, traumatic brain injury, and spinal cord injury).8 VPA also exerts neuroprotective effects in neurodegenerative diseases, including Parkinson disease and Alzheimer disease.9-12

Glaucoma, a neurodegenerative disease, is one of the leading causes of vision loss. It is estimated that this condition will affect more than 80 million people worldwide by 2020, with at least 6 to 8 million of them becoming bilaterally blind.13 Glaucoma is characterized by progressive degeneration of retinal ganglion cells (RGCs) and their axons, usually in association with elevated intraocular pressure. There are several animal models of glaucoma, including DBA/2J.
mice and inducible models such as cauterization of episcleral veins. Normal tension glaucoma is a type of glaucoma with statistically normal intraocular pressure; the occurrence rate seems to vary according to race. We have previously reported that loss of glutamate transporters (EAAC1 or GLAST) in mice leads to RGC degeneration similar to normal tension glaucoma, and these animal models have been useful in examining potential therapeutic targets. Acute models of RGC death are also available, including intravitreal injection of toxins such as 6-OHDA or staurosporine. NMDA is a synthetic compound that selectively activates NMDA receptors (which are a subtype of glutamate receptors), and it mimics the action of glutamate. Excessive activation of glutamate receptors induces a steep rise in intracellular calcium levels and causes excitotoxic cell death. Neuroprotection is a key aspect for development of glaucoma therapy. Indeed, inhibition of NMDA receptors has been a potential therapeutic target for glaucoma. The NMDA antagonist memantine showed promising neuroprotective effects in preclinical studies, although it was not successful in recent clinical trials.

Brain-derived neurotrophic factor (BDNF) is known to regulate neural cell survival, mainly by activating tropomyosin receptor kinase B (TrkB) receptors. Several lines of evidence support a key role for BDNF–TrkB signaling in survival of adult RGCs in acute and chronic models of optic nerve damage. Gene therapy with BDNF was effective in protecting RGCs in experimental glaucoma, suggesting the BDNF–TrkB signaling pathway as a potential therapeutic target for treatment of glaucoma. In the present study, we investigated if VPA protects RGCs from excitotoxic damage using an excitotoxicity model induced by intravitreal injection of NMDA. We examined the effects of VPA using histological techniques as well as in vivo spectral-domain optical coherence tomography and multifocal electroretinography. We provide direct evidence that stimulation of neuronal TrkB receptor signaling is one of the underlying molecular mechanisms for VPA-mediated neuroprotection in the retina.

Materials and Methods

Animals

Experiments were performed using C57BL/6J mice (CLEA Japan, Tokyo, Japan) or TrkB<sup>cre</sup>/lox; c-<i>kit-Cre</i><sup>+</sup> (TrkB<sup>−/−</sup> KO) mice and their WT littermates, in accordance with the Tokyo Metropolitan Institute of Medical Science Guidelines for the Care and Use of Animals. Light intensity inside the cages ranged from 100 to 200 lux and a 12 hours light/12 hours dark cycle was maintained.

Drug Treatment

Mice were anesthetized by intraperitoneal injection of 87.5 mg/kg sodium pentobarbital, and intravitreal injections were performed under a microsurgical microscope (Olympus Corporation, Tokyo, Japan) using a glass microsyringe with a 33-gauge needle (Ito Corporation, Shizuoka City, Japan). Eyes were punctured at the upper temporal limbus and a volume of 2 μL of phosphate-buffered saline (PBS), VPA (75 mmol/L in PBS) (Sigma-Aldrich, Tokyo, Japan), NMDA (1 mmol/L in PBS) (Sigma-Aldrich), or NMDA + VPA (1 mmol/L and 75 mmol/L in PBS, respectively) was injected. To allow diffusion of the solution, the needle was kept inside the eye for approximately 1 minute after the delivery. Mice were allowed to fully recover on a heating pad set at 37°C. The concentrations of the drugs were selected based on our preliminary studies evaluating a range of concentrations (data not shown).

Imaging Acquisition with SD-OCT

Mice were anesthetized by intraperitoneal injection of 87.5 mg/kg sodium pentobarbital, and spectral-domain optical coherence tomography (SD-OCT) examinations using an RS-3000 system (Nidek, Gamagori, Japan) were performed to monitor retinal degeneration in vivo. For fundus imaging, polymethyl methacrylate contact lenses optimal for mice (Unicon, Osaka, Japan) were placed on the corneas. Use of the contact lenses prevents anesthesia-induced cataract progression. A 60D adaptor lens was placed on the objective lens of the Multiline OCT to focus on the mouse retina (Volk Optical, Mentor, OH). All of the images were location-matched, scanning vertically through the center of the optic nerve head at 3 disk diameter lengths above the optic nerve head. The average thickness of the ganglion cell complex (ie, between the internal limiting membrane and the interface of the inner plexiform layer and the inner nuclear layer) was measured. The maximum number of B-scans set by the manufacturer (ie, 50 for line scans) was used for averaging.

Histological Analysis

At the end of the experimental period, mice were sacrificed and perfused with Zamboni’s fixative (2% paraformaldehyde and 15% picric acid in 0.1 mol/L phosphate buffer). Eyes were enucleated and postfixed for 2 hours in 3% glutaraldehyde solution (3% glutaraldehyde, 9% formaldehyde, 37.5% ethanol, and 12.5% acetic acid in distilled water). Paraffin-embedded retinal sections (7 μm thick) were cut through the optic nerve and stained with hematoxylin and eosin. The extent of retinal degeneration was quantified in two ways. First, the number of neurons in the ganglion cell layer (GCL) was counted from one ora serrata through the optic nerve to the other ora serrata in a section. Second, in the same section, the thickness of the inner retinal layer (ie, between the internal limiting membrane and the interface of the outer plexiform layer with the outer nuclear layer) was measured.
Retrograde RGC Labeling

Mice were deeply anesthetized with isoflurane (Intervet, Tokyo, Japan) and then received intravitreal injection of PBS, NMDA, or NMDA+VPA as described in Drug Treatment. Immediately afterwards, the mice were placed on a stereotaxic frame and received an injection of 2 μL Fluoro-Gold (Fluorochrome, Englewood, CO) hydroxystilbamidine (2% in 10% dimethyl sulfoxide) into the superior colliculus. At 7 days after Fluoro-Gold application, the mice were sacrificed, eyes were enucleated, and retinas were isolated for whole-mount preparation. Retinas were fixed in 4% paraformaldehyde in a 0.1 mol/L phosphate buffer solution for 1 hour and mounted on a glass slide with a Vectashield mounting medium (Vector Laboratories, Burlingame, CA); the RGC density was then evaluated under a fluorescence microscope. Three standard areas (0.04 mm²) of each retina at a point 0.1 mm from the optic disk were randomly chosen. Fluoro-Gold-labeled cells were counted, and the average number of RGCs per square millimeter was calculated.

Multifocal Electroretinography

Mice were anesthetized by intraperitoneal injection of 87.5 mg/kg sodium pentobarbital. The pupils were dilated with 0.5% phenylephrine hydrochloride and 0.5% tropicamide. Multifocal electroretinograms were recorded using a VERIS 6.0 system (Electro-Diagnostic Imaging, Redwood City, CA). The visual stimulus consisted of seven hexagonal areas scaled with eccentricity. The stimulus array was displayed on a high-resolution black-and-white monitor driven at a frame rate of 100 Hz. The second-order kernel, which is impaired in patients with glaucoma, was analyzed as previously reported.

Cell Culture

Müller cells were isolated as described previously. Müller cells derived from WT mice were stimulated with 0, 0.1, or 1 mmol/L VPA for 12 or 24 hours and processed for quantitative real-time PCR analyses.

Quantitative Real-Time PCR

Quantitative real-time PCR was performed using an ABI 7300 real-time PCR system (Life Technologies, Carlsbad, CA) with a Power SYBR Green PCR master mix (Life Technologies) as described previously. cDNA reverse-transcribed from total RNA was amplified using primers specific for BDNF (sense, 5'-ATGCCGCAAAACATGTCTATGAG-3'; antisense, 5'-TGACCCACTGCTAATCTGCTA-3'), nerve growth factor (NGF; sense, 5'-CGACTCCAACACTGGAAC-TCA-3'; antisense, 5'-GCCTGCTTCTCATCTGTGTTACA-3'), glial cell-derived neurotrophic factor (GDNF; sense, 5'-GGGCTACCTTGTCATTAGCAC-3'; antisense, 5'-GGCCATTGTGCTACTGTCAGG-3'), ciliary neurotrophic factor (CNTF; sense, 5'-GGTGACTTCCATGCAATTACA-3'; antisense, 5'-CTGTCCAGGCGCCATTAC-3'), and inducible nitric oxide synthase (sense, 5'-ACTGTGTCGGTG-3').
GAGTTCT-3′; antisense, 5′-GGCAGCCTCTTGTCTTT-GAC-3′), and GAPDH (sense, 5′-TGCACCACCAACTGCT- TAG-3′; antisense, 5′-GGATGCAGGGATGATGTTC-3′).

Data were normalized to the level of GAPDH mRNA.

Immunohistochemistry

Mice received intravitreal injection of PBS, NMDA, or NMDA+VPA as described in Drug Treatment and were perfused with Zamboni’s fixative at 12 hours. Eyes were enucleated, postfixed in Zamboni’s fixative for 1 hour, and saturated in a sucrose buffer (30% sucrose in a 0.1 mol/L phosphate buffer). Retinal cryostat sections, 10 μm thick, were prepared and examined by immunostaining as described previously,35 using a 4-hydroxy-2-nonenal mouse monoclonal antibody (MHN-020P, 2 μg/mL) (Japan Institute for the Control of Aging, Shizuoka City, Japan).

Statistical Analysis

For statistical comparison of two samples, we used a two-tailed Student’s *t*-test. Data are expressed as means ± SEM. *P* < 0.05 was regarded as statistically significant.

Results

VPA Suppresses NMDA-Induced Retinal Degeneration

A single intravitreal injection of NMDA induces retinal degeneration, particularly in the GCL, and this experimental strategy is useful for investigating neuroprotective mechanisms that may be effective in glaucoma therapy.24,25 To examine the effects of VPA on this NMDA excitotoxicity model, we injected NMDA intravitreally, with or without VPA. First, we used SD-OCT to monitor the degree of retinal degeneration over a course of 2 weeks. SD-OCT acquires cross-sectional tomographic images of the retina non-invasively, allowing monitoring of the retinal morphology in live subjects, and recent advances in technology have enabled its use in experimental animals. The SD-OCT images revealed that the thickness of the ganglion cell complex was significantly reduced at days 7 and 14 after NMDA injection, and these reductions were suppressed in the presence of VPA (Figure 1). We then examined histopathology of the retina after injection of NMDA with or without VPA. A single intravitreal injection of NMDA clearly decreased the number of surviving neurons in the GCL, and this effect was ameliorated by simultaneous injection of VPA (Figure 2, A and B). In addition, the thickness of the inner retinal layer was significantly reduced after NMDA injection, and this effect also was suppressed by VPA (Figure 2, A and C). We next specifically labeled RGCs by retrograde labeling with Fluoro-Gold to determine the effects of VPA on RGC survival after NMDA injection. Consistent with the trends observed in the number of cells in the GCL, NMDA induced a significant loss of RGCs and again VPA protected RGCs from this damage (Figure 3). Taken together, these results demonstrate histologically that VPA suppresses retinal degeneration and protects RGCs from NMDA-induced neurotoxicity.

Figure 4  VPA ameliorates NMDA-induced loss of visual function in mice. A: Representative three-dimensional plots of averaged visual responses of the second-order kernel as examined by multifocal electroretinography at 14 days after intravitreal injection of PBS, 1 mmol/L NMDA, or 1 mmol/L NMDA + 75 mmol/L VPA. Retinal function is scored in nanovolts per degree squared; higher values indicate highly sensitive visual function and lower values indicate retinal dysfunction. B: Corresponding quantitative analyses. Data are expressed as means ± SEM. *P* < 0.01. **P* < 0.001. 2K, second-order kernel; deg², degree squared; NMDA, N-methyl-D-aspartate; PBS, phosphate-buffered saline; RGC, retinal ganglion cell; VPA, valproic acid.

GAGTTCT-3′; antisense, 5′-GGCAGCCTCTTGTCTTT-GAC-3′, and GAPDH (sense, 5′-TGCACCACCAACTGCT-TAG-3′; antisense, 5′-GGATGCAGGGATGATGTTC-3′). Data were normalized to the level of GAPDH mRNA.
VPA Ameliorates NMDA-Induced Loss of Visual Function

To determine if the observed changes in cell numbers due to NMDA with and without VPA reflect functional aspects, we examined visual function using multifocal electroretinography, which is a vital tool for substantiating histological observations with physiological phenomena in the retina. Multifocal electroretinography is an established noninvasive method for effectively measuring retinal activity in living animals, and it allows isolation of the RGC contribution. We analyzed the second-order kernel, which appears to be a sensitive indicator of inner retinal dysfunction and is impaired in glaucoma patients. The response topography demonstrating the second-order kernel component revealed that NMDA significantly impaired visual responses in all visual fields at day 14, compared with vehicle, and VPA markedly suppressed these effects (Figure 4). These results point to a very important conclusion, that the neuroprotective effects of VPA after NMDA-induced neurotoxicity are functionally significant.

VPA Promotes Up-Regulation of Neurotrophic Factors in Müller Glial Cells

We have previously identified important roles of Müller glial neurotrophic factors in protection of retinal neurons. We therefore speculated that one of the VPA-mediated neuroprotective mechanisms might involve up-regulation of neurotrophic factors in Müller cells and, in particular, that an increase in neurotrophic factor levels in Müller cells might in turn stimulate survival of RGCs. VPA treatment produced a time- and dose-dependent increase in BDNF expression in cultured Müller cells, and the higher dose of VPA (1 mmol/L) also up-regulated NGF expression at 48 hours (Figure 5, A and B). VPA at the doses and time points investigated did not affect the expression level of GDNF or CNTF (Figure 5, C and D). These results suggest that VPA up-regulates BDNF and NGF in Müller cells and exerts neuroprotective effects on RGCs indirectly.

VPA Protects RGCs through Neuronal TrkB Signaling

The VPA-stimulated up-regulation of neurotrophic factors in Müller cells suggested that VPA may indirectly activate the corresponding signaling pathways in RGCs for protection against NMDA-induced neurotoxicity. Because BDNF showed a significant dose-dependent up-regulation, we focused on the BDNF signaling pathway. To examine the role of neuronal BDNF—TrkB signaling in VPA-mediated neuroprotection, we used conditional knockout (KO) mice in which TrkB is deleted from two types of retinal neurons, RGCs and amacrine cells (TrkB c-kit KO mice). We first monitored the effects of VPA on retinal degeneration after NMDA injection in TrkB c-kit KO mice.

Figure 5 VPA stimulates up-regulation of neurotrophic factors in Müller cells in mice. A–D: Expression of neurotrophic factors in Müller cells at 24 and 48 hours after stimulation with 0.1 or 1 mmol/L VPA. Relative mRNA expression levels of BDNF (A), NGF (B), GDNF (C), and CNTF (D). GAPDH was used as an internal control and results are normalized to controls (GAPDH mRNA expression). Data are expressed as means ± SEM. n = 4. *P < 0.05, **P < 0.01. BDNF, brain-derived neurotrophic factor; CNTF, ciliary neurotrophic factor; GDNF, glial cell-derived neurotrophic factor; NGF, nerve growth factor; PBS, phosphate-buffered saline; VPA, valproic acid.

Figure 6 In vivo imaging of the retina demonstrates that VPA-mediated suppression of retinal degeneration is significantly reduced in TrkB c-kit knockout mice. A: Representative OCT cross-sectional images of TrkB c-kit knockout mouse retinas at 7 and 14 days after intravitreal injection of PBS, 1 mmol/L NMDA, or 1 mmol/L NMDA + 75 mmol/L VPA. B: Corresponding longitudinal evaluation of GCC thickness as a percentage of the PBS control. Data are expressed as means ± SEM. n = 6. *P < 0.05, **P < 0.01. GCC, ganglion cell complex; INL, inner nuclear layer; NMDA, N-methyl-D-aspartate; OCT, optical coherence tomography; ONL, outer nuclear layer; PBS, phosphate-buffered saline; VPA, valproic acid.
VPA Protects RGCs from Excitotoxicity

Discussion

In the present study, we have demonstrated that the widely prescribed antiepileptic drug VPA protects RGCs from NMDA-induced neurotoxicity, mainly through stimulation of neuronal BDNF—TrkB signaling. We examined the neuroprotective effects of VPA in terms of both histology and function, and used a noninvasive in vivo imaging technique for monitoring retinal degeneration over time in the same animal. We show that VPA up-regulates BDNF and NGF expression in Müller cells. Using TrkB<sup>−/−</sup> KO mice, we provide direct evidence that the neuronal TrkB receptor plays an important role in VPA-mediated neuroprotection against NMDA neurotoxicity in the retina.

VPA Reduces NMDA-Induced Oxidative Stress

Our findings so far had demonstrated the importance of neuronal BDNF—TrkB signaling. However, the fact that the neuroprotective effects of VPA were not completely abolished in TrkB<sup>−/−</sup> KO mice suggests that there are other pathways for VPA-mediated neuroprotection. One of the major causes of cell death associated with NMDA neurotoxicity is induction of oxidative stress. We therefore investigated if VPA modulates the oxidative stress level after NMDA injection in the retina. We first examined the retinal expression of 4-hydroxy-2-nonenal, which is a common byproduct of lipid peroxidation during oxidative stress and provides a reliable measure of oxidative stress, after NMDA injection with or without VPA. In the NMDA-treated retina, there was a significant increase in expression of 4-hydroxy-2-nonenal in the GCL, compared with the PBS-treated retina, indicative of increased oxidative stress, but 4-hydroxy-2-nonenal expression was significantly suppressed in the presence of VPA (Figure 8, A and B). In addition, the expression of inducible nitric oxide synthase, which is usually induced in an oxidative environment and so is a good indicator of oxidative stress, was significantly increased in the NMDA-treated retina, but this effect was suppressed in the VPA-treated retina (Figure 8C). These results suggest that inhibition of oxidative stress is another mechanism for VPA-mediated neuroprotection against NMDA neurotoxicity in the retina.
NMDA neurotoxicity in the retina. We also show an alternative neuroprotective mechanism in which VPA suppresses oxidative stress after induction of NMDA neurotoxicity in the retina.

VPA is an effective histone deacetylase inhibitor,\(^6,7\) and treatment with VPA increases levels of neurotrophic factors in mouse and rat brain.\(^40–42\) In the retina, VPA up-regulated the expression of BDNF and TrkB after optic nerve injury, and there was an increased acetylation level of histone H3 accompanied by increased transcriptional activity of the BDNF promoter in the retina.\(^43\) These results suggest that the VPA-mediated up-regulation of BDNF in Müller cells observed in the present study is likely to be due to elevated BDNF promoter activity through direct inhibition of histone deacetylase. Neuroprotection by stimulation of BDNF–TrkB signaling has been well established. Interestingly, TrkB\(^{C-kit}\) KO mice demonstrated increased susceptibility to NMDA-induced neurotoxicity (Figures 6 and 7),\(^33\) indicating the importance of the intrinsic BDNF–TrkB signaling pathway in neuroprotection in the retina. Recently, several selective TrkB agonists have been proposed as therapeutic agents for neurodegenerative diseases.\(^34,42\) Based on the evidence that neurotrophic factors protect the retina from various pathological conditions,\(^46\) development of such compounds that mimic some of the beneficial effects of neurotrophic factors is of clinical interest. Interestingly, a novel phosphate–borane complex was reported to promote RGC protection through induction of BDNF,\(^47\) which supports our present findings and also supports the idea that up-regulation of BDNF and increased signaling through TrkB by VPA may be effective for treatment of glaucoma.

Müller cells are the principal glial cells in the retina, and recent studies show that their roles extend beyond supporting retinal structure and homeostasis.\(^7,8,49\) For example, prolonged gene delivery of BDNF in Müller cells enhanced neuronal survival after optic nerve injury.\(^50\) We have previously reported important roles of neurotrophic factors in Müller cells in protection of photoreceptors and RGCs.\(^23,33,36\) Our present findings suggest a mechanism in which administration of VPA up-regulates BDNF in Müller cells, which in turn stimulates neuronal BDNF–TrkB signaling and thus leads to RGC protection against NMDA-induced neurotoxicity. In addition, our present results demonstrated that VPA increases NGF production in Müller cells. The delay of 48 hours in up-regulation of NGF suggests that its neuroprotective effects on acute RGC death may be limited, but that it may be effective in protecting RGCs from later death. In a recent study, NGF eye drops reduced RGC loss in patients with advanced glaucoma, and long-lasting improvements were observed in visual field, optic nerve function, contrast sensitivity, and visual acuity.\(^71\) Although further studies are required before topical NGF can be considered for clinical application in glaucoma, VPA-induced NGF may be beneficial for RGC protection in human eyes. We have previously demonstrated that brimonidine eye drops stimulate production of NGF, BDNF, and basic fibroblast growth factor in Müller cells and ameliorate retinal degeneration in a murine model of normal tension glaucoma.\(^72\) Thus, in addition to lowering intraocular pressure, combination treatment with VPA and brimonidine may prevent glaucomatous retinal degeneration by stimulating multiple pathways, including glia–neuron interactions.

Oxidative stress is an important risk factor in human glaucoma,\(^52\) and studies with DBA/2J mice, an animal model that recapitulates the slow and progressive nature of human glaucoma, demonstrated that the antioxidant z-lipoic acid protects RGCs in the glaucomatous retina.\(^53\) VPA has been reported to enhance activities of several enzymes with antioxidant properties in the ischemic retina.\(^54\) Consistent with our present findings (Figure 8), antioxidant properties of VPA have been demonstrated in brain and retina in a stroke model\(^55,56\) and also in spinal cord injury.\(^57\) These studies support our conclusion that suppression of oxidative stress is one of the neuroprotective mechanisms for VPA in the NMDA excitotoxicity model.

We note some limitations to the present study. First, the neuroprotective action of VPA involves multiple mechanisms.\(^58\) Although our findings in TrkB\(^{C-kit}\) KO mice suggest that the BDNF–TrkB signaling pathway plays a major role in VPA-mediated neuroprotective effects on NMDA-induced neurotoxicity in the retina, and although we also demonstrated increased glial NGF expression and reduced oxidative stress, we cannot eliminate the possibility that other protective mechanisms are also involved. One possible mechanism may be a direct effect of VPA on neuronal excitability. VPA inhibits the activity of voltage-gated cation channels,\(^59,60\) suggesting that NMDA neurotoxicity in the present study may also be suppressed through this mechanism. Thus, our present results do not fully explain the neuroprotective mechanisms associated with VPA. Second, the NMDA excitotoxicity model mimics some key features observed in human glaucoma, including loss of RGCs and increased oxidative stress, but the underlying molecular mechanisms are not quite the same as for pathogenesis of human glaucoma. Previous studies have indicated that VPA protects RGCs from optic nerve injury—induced cell death.\(^45,61\) The optic nerve injury model is an animal model of glaucoma that allows investigation of mechanisms underlying death of retinal neurons.\(^34,62\) but this model is not sufficient to represent fully the pathogenesis of glaucoma. It would therefore be worthwhile to investigate if VPA can ameliorate glaucomatous retinal degeneration in other animal models of glaucoma.

In summary, we have shown that VPA suppresses RGC death from NMDA-induced neurotoxicity and we provide direct evidence for the role of neuronal TrkB in VPA-mediated neuroprotection. Our findings emphasize the importance of glia–neuron crosstalk in neuroprotection and raise an interesting possibility that VPA may be effective for treatment of glaucoma.
