Blockade of the renin-angiotensin system attenuates the progression of experimental and clinical Alport syndrome (AS); however, the underlying mechanism(s) remains largely unknown. We evaluated the renin-angiotensin system in 4- and 7-week-old homozygous for collagen type IV, α3 gene (Col4a3/C0/C0) and wild-type mice, a model of AS characterized by proteinuria and progressive renal injury. Renal angiotensin (Ang) II levels increased, whereas renal Ang-(1–7) levels decreased in 7-week-old Col4a3/C0/C0 mice compared with age-matched controls; these changes were partially reversed by recombinant angiotensin-converting enzyme 2 (ACE2) treatment. The expression of both the angiotensinogen and renin protein increased in Col4a3/C0/C0 compared with wild-type mice. Consistent with the Ang-(1–7) levels, the expression and activity of kidney ACE2 decreased in 7-week-old Col4a3/C0/C0 mice compared with wild-type mice. The urinary excretion rate of ACE2 paralleled the decline in tissue expression. Expression of an Ang II-induced gene, heme oxygenase-1, was up-regulated in the kidneys of 7-week-old Col4a3/C0/C0 mice compared with wild-type mice by microarray analysis. Heme oxygenase-1 (HO-1) protein expression was increased in kidneys of Col4a3/C0/C0 mice and normalized by treatment with ACE inhibitor. Urinary HO-1 excretion paralleled renal HO-1 expression. In conclusion, progressive kidney injury in AS is associated with changes in expression of intrarenal renin Ang system components and Ang peptides. HO-1 and ACE2 may represent novel markers of AS-associated kidney injury, whereas administration of recombinant ACE2 and/or Ang-(1–7) may represent novel therapeutic approaches in AS. (Am J Pathol 2015, 185: 1423–1435; http://dx.doi.org/10.1016/j.ajpath.2015.01.021)

Alport syndrome (AS) is a hereditary nephropathy characterized by progressive kidney disease.1,2 AS is caused by mutations in type IV collagen genes that encode major constituents of glomerular basement membranes.3,4 Inhibitors of renin-angiotensin system (RAS), including angiotensin-converting enzyme (ACE) inhibitors or angiotensin (Ang) II receptor blockers, were found to slow kidney disease progression in both experimental and clinical AS.5,6 The effect of RAS blockade, particularly ACE inhibitors, suggests that Ang peptide processing in the kidney is important for the pathogenesis of AS.

Supported by operating grants from the Canadian Institutes of Health Research (CIHR), the Kidney Foundation of Canada (KFoC), and the Korea Research Foundation [funded by the Korean Government (MOEHRD) and the Basic Research Promotion Fund grant KRF-20100008732]; by funding from the Ontario Graduate Student Program (F.F.); and by a research fellowship from the KFoC and the Clinician Scientist Training Program at the University of Toronto (A.K.). Disclosures: None declared.
in the pathogenesis of progressive kidney injury in experimental AS. Studies have reported an important role for local Ang peptide processing in tissue responses to RAS activation. In particular, the ACE homolog, ACE2, may play a critical role, through Ang II degradation or Ang-(1–7) generation. The expression and activity of ACE2 were found to modulate the kidney response to injury in settings as diverse as ischemia reperfusion injury, unilateral ureteral obstruction, and diabetic nephropathy.

To better understand the mechanism that link RAS activation to injury in AS, we characterized gene and protein expression of RAS components in the kidney of mice homozygous for collagen, type IV, α3 gene (Col4a3−/−), with a focus on ACE2 tissue expression, activity, and urinary excretion. We also measured plasma and intrarenal Ang II and Ang-(1–7) peptide levels and correlated these peptide levels with a previously described Ang II gene/protein signature. Our work finds diminished ACE2 expression and activity in kidneys of Col4a3−/− mice, associated with increased Ang II and decreased Ang-(1–7) levels. These abnormalities are further associated with increased tissue and urine levels of Ang II gene/protein signature and can be partially corrected by treatment with recombinant ACE2 (rACE2).

Materials and Methods

Ethics Statement

All experiments were conducted according to the guidelines of the University of Toronto Animal Care Committee.

Animals

Wild-type (WT) and Col4a3−/− knockout (KO) mice on 129X1/SvJ background were purchased from The Jackson Laboratory (Bar Harbor, ME), housed at the Division of Comparative Medicine at the University of Toronto, and fed standard mouse chow with free access to water. Only male mice were used in this study. Genotype for Col4a3−/− mice was verified by tail clip genotyping by using the following primers: common, 5′-CCAGGCTTAAAGGGAAATCC-3′; WT reverse, 5′-TGCTCTCTCAAATGCACCAG-3′; and mutant reverse, 5′-GCTATCAGGACATAGTGTTGG-3′.

Biochemistry

Blood samples were collected from carotid artery with Microvette (Sarstedt Inc., Montreal, QC, Canada) at time of sacrifice. Serum was isolated by centrifugation of blood samples at 2000 × g for 5 minutes at room temperature and stored at −80°C until use. Serum creatinine assessments were done at the Toronto Centre for Phenogenomics (Toronto, ON, Canada). Albumin excretion rates were determined from 24-hour urine collections in 4- and 7-week-old mice with the use of kits (Albuwell M ELISA; Exocell, Philadelphia, PA).

Histology and Immunohistochemistry

The right kidney was harvested and transversely sectioned into three approximately equal portions. The two polar portions were snap-frozen, and the middle portion was placed into 10% neutral-buffered formalin (Sigma-Aldrich, St. Louis, MO) for histology and immunohistochemistry analyses. Fixed kidney tissue was paraffin-embedded, sectioned, stained, and scanned. Periodic acid-Schiff–stained sections (3 μm) were used to assess histopathologic injury. The following primary antibodies were used for immunohistochemistry: ACE and renin (Santa Cruz Biotechnology, Santa Cruz, CA), ACE2 (R&D Systems, Minneapolis, MN), and angiotensinogen (AGT) and heme oxygenase-1 (HO-1; Abcam, Inc., Cambridge, MA). Quantitation of ACE and ACE2 on positively stained area was measured by a Positive Pixel Count algorithm of Aperio Image Scope software version 11.1 (Aperio Technologies, Inc., Vista, CA). Semiquantitative analysis was performed for HO-1 stain by counting the average number of positively stained tubules within 10 high-power fields of the renal cortex.

Microarray

We performed global gene profiling of renal cortical samples from male Col4a3−/− mice and WT mice at 4 and 7 weeks of age in a 2 × 2 factorial design (n = 8 per group). Gene expression was analyzed with the Affymetrix Mouse Gene 2.0 ST array (Affymetrix, Santa Clara, CA). Renal cortex was resected and incubated in RNAlater at 4°C overnight and then stored at −80°C until further analyses. Probes were synthesized and labeled with Ambion WT Expression, GeneChip WT Terminal Labeling kits (Ambion, Austin, TX). Affymetrix Mouse Gene 2.0 ST array that feature probe sets for 28,137 coding transcripts, 7103 noncoding transcripts, 2000 long intergenic noncoding transcripts was used for the microarray study. Affymetrix Expression Console software version 1.3.1 was used to assess microarray data quality and to perform RNA signal value normalization.

Ang II and Ang-(1–7) Peptide Measurement

The concentration of plasma and renal parenchymal Ang II and Ang-(1–7) were determined by Ang II and Ang-(1–7) enzyme immunoassay kits (Peninsula Laboratories, LLC, San Carlos, CA). According to the manufacturer, the Ang II-binding antibody does not cross-react with Ang I or Ang-(1–7), and Ang-(1–7)–binding antibody also does not cross-react with Ang I or Ang II. Tissue was prepared as follows: snap-frozen kidney tissue was homogenized in ice-cold methanol on ice and centrifuged at 12,000 × g for 10 minutes at 4°C. The supernatant fluid was collected and dried by centrifugal evaporation. Dried samples were reconstituted with the enzyme immunoassay buffer supplied by the manufacturer and used for Ang II and Ang-(1–7) measurement. Protein concentrations were determined by the Bradford assay (Bio-Rad Laboratories, Inc., Minneapolis, MN), and angiotensinogen (AGT) and heme oxygenase-1 (HO-1; Abcam, Inc., Cambridge, MA). Quantitation of ACE and ACE2 on positively stained area was measured by a Positive Pixel Count algorithm of Aperio Image Scope software version 11.1 (Aperio Technologies, Inc., Vista, CA). Semiquantitative analysis was performed for HO-1 stain by counting the average number of positively stained tubules within 10 high-power fields of the renal cortex.
Real-Time PCR

RNA was extracted from kidney cortex by using the RNeasy Mini kit and was reverse transcribed into cDNA with the QuantiTect Reverse Transcription kit (Qiagen Canada, Mississauga, ON, Canada). mRNA expression levels for renin, AGT, ACE, ACE2, Ang II type 1 receptor (AT-1R), and Mas receptor (MasR) were quantified by real-time PCR (TaqMan) by using a sequence detection system (ABI Prism 7900; Applied Biosystems, Foster City, CA) as previously described. Specific mouse primer sets were purchased from Applied Biosystems.

Western Blot Analysis

Mouse kidney tissue was washed with ice-cold phosphate-buffered saline twice. Renal tissue was placed in modified RIPA buffer at a concentration of 1 mg/50 µL buffer [150 mmol/L sodium chloride, 50 mmol/L Tris-HCl (pH 7.4), 1 mmol/L EDTA, 1% v/v Triton X-100, 1% w/v sodium deoxycholic acid, 0.1% v/v SDS]. Tissues were then sonicated twice for 10 seconds and incubated on ice for 30 minutes. After centrifugation at 14,000 rpm for 10 minutes, supernatant fluid was transferred to a tube with loading buffer and boiled for 5 minutes. Proteins in tissue lysates were separated by 6% to 12% SDS-PAGE gel, blotted onto polyvinylidene difluoride membrane and detected with an enhanced chemiluminescence system kit (Millipore Corp., Billerica, MA). Densitometry was calculated by Scion Image software (Scion Corp., Frederick, MD). The following primary antibodies were used for Western blot analyses: ACE, AT-1R, renin, and MasR (Santa Cruz Biotechnology); ACE2 (R&D Systems); AGT and HO-1 (Abcam, Inc.).

ACE Activity

Kidney ACE activity was measured by the rate of generation of His-Leu from Hip-His-Leu (Sigma-Aldrich) substrate by using fluorometric assay. Tissue was homogenized in ice-cold 50 mmol/L potassium phosphate buffer, pH 7.5. An aliquot of the homogenized samples was then incubated with 3.5 mmol/L Hip-His-Leu for 10 minutes in 37°C shaking water bath. The reaction was stopped by adding 340 mmol/L NaOH. Blank controls were treated in the same fashion, with the exception that Hip-His-Leu was added after sodium hydroxide treatment. We added 1% phthalaldehyde (Sigma-Aldrich) to the aliquots for 10 minutes before the color reaction was stopped with 3N HCl. Fluorescence was measured with an FLX800 microplate fluorescence reader (BioTek Instruments Inc.) at 355 nm of excitation and 520 nm of emission wavelength.

ACE2 Activity

Kidney ACE2 activity was determined after incubation with the intramolecularly quenched synthetic ACE2-specific substrate Mca-APK-Dnp (Anaspec, Inc., Fremont, CA). The measurements were performed in black microtiter plates with a 100-µL total volume. Briefly, 1 µg of total protein from tissue homogenate (renal cortex) was added to wells that contain 10 µmol/L ACE2 substrate. After incubation at ambient temperature for 1 hour, fluorescence was measured with an FLX800 microplate fluorescence reader (BioTek Instruments Inc.) at 330 nm of excitation and 390 nm of emission wavelength. Total fluorescence was corrected for protein content (in tissue homogenates) after subtracting blank values.

Values are means ± SEM. BW and KW were recorded at time of sacrifice. Urine output was measured for 24 hours the day before sacrifice. Cr levels were measured in frozen plasma samples.

*P < 0.05 versus WT.

BW, body weight; KO, homozygous for collagen, type IV, α3 gene; KW, average kidney weight; P<sub>L</sub>, plasma creatinine; UalbV, urine albumin over 24 hours; WT, wild-type.

**Chymase Activity**

Chymase activity was measured with a colorimetric assay. The measurements were performed in 96-well plates with a 100-μL total volume. Briefly, 33 μL of protein from tissue homogenate (renal cortex) was added to wells that contained 3 μL of N-Succinyl-Ala-Ala-Pro-Phe p-nitroanilide (chymase substrate) and 64 μL of assay buffer (Sigma-Aldrich). Samples were mixed and equilibrated to 37°C in the plate reader chamber (1 to 2 minutes). Absorbance was measured at 450 nm and normalized to protein content after subtracting blank values.

**Urinary ACE2 and HO-1 ELISA**

The amount of ACE2 present in urine specimens was quantified with a commercial ELISA kit according to the protocol provided by the supplier (Bluegene, Shanghai, China). A standard curve was generated by performing 1:2 serial dilutions of mouse recombinant ACE2 (50 ng/mL), provided with the kit, with the sensitivity 0.1 ng/mL. The amount of ACE2 obtained by ELISA was normalized to the urine creatinine concentration, and was reported as ng/μmol creatinine.

Mouse HO-1 ELISA kit (USCN Life Science Inc., Houston, TX) was used to measure urine HO-1 protein concentration. Mouse urine samples were thawed overnight at 4°C and then centrifuged for 20 minutes at 1000 × g. Pellets were discarded, and urine samples were diluted twice and were assayed per the manufacturer’s instructions. Final HO-1 concentrations were expressed as ng/mmol creatinine.

**Cell Culture**

Primary human renal proximal tubular epithelial cells (PTECs) were purchased from Lonza Walkersville Inc. (Walkersville, MD). Cells were cultured as described before. Briefly, tubular cells were cultured in Dulbecco’s Modified Eagle Medium/F12, supplemented with 17% v/v fetal bovine serum, 10 ng/mL epidermal growth factor, 5 μg/mL transferrin, 5 μg/mL insulin, 0.05 μmol/L hydrocortisone, 50 U/mL penicillin, and 50 μg/mL streptomycin. Cells were grown in T75 flasks to approximately 80% confluence. They were then serum-deprived for 18 hours and were subjected to control (serum-free medium alone), 10⁻⁷ mol/L Ang II, 10⁻⁷ mol/L Ang-II + 10⁻⁹ mol/L Ang-(1–7), or 10⁻⁷ mol/L Ang-II + 20 μmol/L AT-1R blocker (losartan; Sigma-Aldrich) treatments for 8 hours. Cells were then washed three times with phosphate-buffered saline, harvested, and frozen at −80°C until further analysis. All cells were cultured in a humidified incubator at 37°C and 5% CO₂.

**Generation and Characterization of mrACE2**

Murine rACE2 (mrACE2) was generously donated by Dr. Gavin Yadram Oudit (The University of Alberta, Edmonton, Alberta, Canada). Briefly, the extracellular domain of murine ACE2 (amino acid residues 1 to 740) was expressed recombinantly in Chinese hamster ovary cells under serum-free conditions in a chemically defined medium. The expression product was purified to homogeneity by applying the definitive production process. Quality of the mrACE2 was tested by size exclusion chromatography—high-performance liquid chromatography with the use of a MapPac-SEC1, 5 μm, 300 Å at a flow rate of 0.25 mL/min (APEIRON Biologics, Vienna, Austria). Integration of the signal monitored at 214 nm indicated a purity >99%, the signal monitored at 280 nm also indicated a purity >99%.

**Treatment with ACE Inhibitor or mrACE2**

Ramipril (Sigma-Aldrich) was added to the drinking water and replaced twice a week, starting at 4 weeks of age to Col4a3⁻/⁻ mice for a period of 3 weeks. Ramipril remains stable in water for >4 days at room temperature. Daily fluid intake was measured in this 3-week period to ensure a daily dose of 10 mg/kg per day of ramipril over the 3-week period. Col4a3⁻/⁻ mice were administered mrACE2 at a dose of 0.5 mg/kg per day, starting at 4 weeks of age for a period of 3 weeks, via osmotic minipump (model 1004; Alzet, Palo Alto, CA).

**Statistical Analysis**

Unless specified otherwise, results are expressed as means ± SEM. Two-tailed Student’s t-test was used for
comparisons between two groups. Nonparametric Mann-Whitney test was used to compare nonnormally distributed data (urine HO-1 protein levels between \textit{Col4a3}^{-/-} and WT mice). One-way analysis of variance was used for comparison of three or more groups. All statistical analyses were done with GraphPad Prism software version 5.0 (GraphPad Software, Inc., La Jolla, CA). The expression of the RAS gene signature was compared with the whole microarray gene signature by \chi^2 test. Two-tailed \( P < 0.05 \) was considered significant.

**Results**

**Whole Mice, Macroscopic, and Microscopic Kidney Examinations**

\textit{Col4a3}^{-/-} mice (KO) were genotyped (Figure 1A), and microarray analysis-derived heat map for collagen-IV \( \alpha_1-\alpha_5 \) gene expression in kidney tissues of 4- and 7-week-old WT and \textit{Col4a3}^{-/-} mice were generated (Figure 1B). As expected, \textit{Col4a3}^{-/-} gene expression was absent in the KO mice. Difference in expression of other collagen-IV \( \alpha \) genes was most pronounced in 7-week-old mice. KO mice indicated absent \( \alpha_4/\alpha_5 \) genes with increased \( \alpha_1/\alpha_2 \) gene abundance compared with WT mice. Urinary albumin excretion was significantly increased even in 4-week-old \textit{Col4a3}^{-/-} mice (Figure 1C). Serum creatinine levels were numerically increased in 7-week-old \textit{Col4a3}^{-/-} mice, although the difference did not reach statistical significance (\( P = 0.18 \)) (Figure 1D). Whole mice and biochemical data for the four groups of mice are shown in Table 1. Body weight was not different in \textit{Col4a3}^{-/-} mice compared with WT mice, but kidney-to-body weight ratio increased significantly in 7-week-old \textit{Col4a3}^{-/-} mice compared with the age-matched WT mice. Histopathologic kidney injury was evident on Periodic acid-Schiff and Masson’s trichrome-stained sections from \textit{Col4a3}^{-/-} mice (Figure 1, E and F), particularly at 7 weeks of age.

**Kidney Ang II and Ang-(1–7) Peptide Levels**

Tissue Ang II and Ang-(1–7) levels were quantified with enzyme immunoassay. Ang II and Ang-(1–7) levels were not significantly different between WT and \textit{Col4a3}^{-/-} mice at 4 weeks of age, whereas Ang II level was significantly higher (Figure 2A) and Ang-(1–7) level was significantly lower in 7-week-old \textit{Col4a3}^{-/-} mice than in WT mice (Figure 2C). An Ang II/Ang-(1–7) ratio that was used to reflect the counterbalancing nature of these peptides further reflected this pattern (Figure 2E). In the plasma, Ang II was increased in 4- and 7-week-old \textit{Col4a3}^{-/-} mice compared with WT mice (Figure 2B). However, neither plasma Ang-(1–7) peptide level nor the Ang II/Ang-(1–7)
ratio were significantly different between the two groups (Figure 2, D and F).

**Kidney AGT and Renin Expression**

We proceeded to systematically examine the expression of RAS components in kidneys of Col4a3−/− and WT mice. We first examined mRNA and protein expression of the two rate-limiting components of RAS peptide generation, namely AGT and renin. Real-time PCR–based gene expression found increased AGT mRNA levels in 7-week-old KO mice compared with age-matched WT mice, whereas no difference was found between 7-week-old WT and KO mice (Figure 3A). AGT protein expression in the kidney is significantly higher in 7-week-old KO than in 7-week-old WT mice (Figure 3C). Renin mRNA is decreased in 4-week-old KO mice compared with age-matched WT mice, whereas expression was similar between 7-week-old WT and KO mice (Figure 3B). Renal renin protein expression is also significantly higher in 7-week-old KO mice than in 7-week-old WT mice, whereas renin protein expression is decreased in 4-week-old KO mice compared with age-matched WT mice (Figure 3D). Immunohistochemistry localized AGT to the proximal tubules, and expression level was consistent with the Western blot analysis (Figure 3E). Renin was localized to juxtaglomerular afferent arteriolar cells, with the most prominent staining in 7-week-old WT mice (Figure 3F).

**Kidney ACE and ACE2 Expression**

We next examined renal expression of ACE and ACE2, two key enzymes in the generation of bioactive RAS peptides. Real-time PCR data indicated that ACE mRNA was significantly lower in 4-week-old Col4a3−/− mice than in WT mice, whereas a nonsignificant trend toward lower ACE expression was found in 7-week-old Col4a3−/− mice than in WT mice (Figure 4A). ACE protein was significantly lower...
in 7-week-old Col4a3−/− mice than in WT mice, whereas no difference was found between 4-week-old Col4a3−/− and WT mice (Figure 4C). ACE was localized to the proximal tubule on immunohistochemistry slides (Figure 4E). Representative images (Figure 4E) and accompanying quantification of ACE-positive area (Supplemental Figure S1A) supported the Western blot analysis—based quantification, with lowest ACE expression in 7-week-old Col4a3−/− mice.

ACE2 indicated a similar pattern of expression as ACE. ACE2 mRNA expression was significantly diminished in 4-week-old Col4a3−/− mice compared with age-matched controls, whereas no difference was found in the expression between 7-week-old Col4a3−/− and WT mice (Figure 4B). ACE2 protein was significantly lower in 7-week-old Col4a3−/− mice than in age-matched WT mice, whereas no difference was found in the expression between 4-week-old mice (Figure 4D). ACE2 was localized to the proximal tubule on immunohistochemistry slides (Figure 4F). Representative images (Figure 4F) and accompanying quantification of ACE2-stained area (Supplemental Figure S1B) supported findings from Western blot analyses, with lowest expression in 7-week-old Col4a3−/− mice.

ACE, ACE2, and Chymase Activity

We found increased Ang II peptide and decreased Ang-(1−7) level in 7-week-old Col4a3−/− mice compared with age-matched controls but decreased expression of ACE and ACE2. We thus directed our attention to the renal enzymatic activity of ACE, ACE2, and another Ang II-generating enzyme chymase. ACE activity was not different in 7-week-old Col4a3−/− mice compared with WT mice (Figure 5A), whereas ACE2 and chymase activity was significantly lower in 7-week-old Col4a3−/− mice than in WT mice (Figure 5B and C). Finally, ACE2 urinary excretion was significantly decreased in 7-week-old Col4a3−/− mice compared with age-matched WT mice (Table 2). ACE, ACE2, and chymase activity in kidney tissue and ACE2 urine excretion were not significantly different between 4-week-old Col4a3−/− and WT mice.

To examine whether ACE2 may regulate the expression of RAS effector peptides, we also measured renal Ang II...
and Ang-(1−7) levels after treatment with mrACE2. Indeed, the elevated Ang II and decreased Ang-(1−7) levels seen in 7-week-old Col4a3−/− mice were partially reversed after mrACE2 administration (Supplemental Figure S2).

Kidney AT-1 and Mas Receptor Expression

The two dominant bioactive peptides of RAS, Ang II and Ang-(1−7), exert their main functions by activating AT-1R and MasR respectively, and so we examined the expression of these two receptors. AT-1R and MasR were not differentially expressed at the level of mRNA in 4- or 7-week-old Col4a3−/− mice compared with WT mice (Figure 6A). In contrast, both AT-1R and MasR proteins were significantly higher in 7-week-old Col4a3−/− mice than in age-matched WT mice. No differences were found in receptor expression between 4-week-old Col4a3−/− and WT mice (Figure 6B).

Correlation with Previously Described Markers of Intrarenal Ang II Activity

Our data indicated dysregulation in RAS components with a significant increase in Ang II and Ang II/Ang-(1−7) ratio in the kidneys of Col4a3−/− mice. Given the potential importance of this imbalance between the two critical effectors of RAS, it would be informative to have markers that could reflect the imbalance.

We have recently identified 83 proteins regulated by Ang II in PTECs.10 We thus examined whether the Ang II-dominant state could be reflected in the expression of these Ang II-regulated proteins. We first examined the mRNA expression of these proteins. Seventy-six of 83 proteins had corresponding mRNAs on the Affymetrix Gene Chip Mouse Gene 2.0 ST arrays (Figure 7). We performed unsupervised hierarchical cluster analysis which found that 30 of 76 genes were significantly up-regulated and 3 genes were significantly down-regulated in 7-week-old Col4a3−/− mice compared with WT mice (Figure 7 and Supplemental Table S1). This number of differentially regulated genes was significantly higher than would be expected from chance alone, when comparing it with the whole Affymetrix Chip that contained 8961 of 41,345 genes that were differentially regulated in Col4a3−/− compared with WT mice at false discovery rate ≤ 5% (χ² statistic, 21.11; P = 4 × 10⁻⁶ for the difference in proportion of differentially regulated genes in Ang II gene set and the whole Affymetrix set). One of our top candidates from previous analyses,10 HO-1 (gene name Hmox1), was also up-regulated in 7-week-old Col4a3−/− mice kidneys. None of the 76 genes were differentially expressed between the 4-week-old Col4a3−/− and WT mice.

In addition, HO-1 protein expression was significantly up-regulated in kidneys of 7-week-old Col4a3−/− mice compared with age-matched controls (Figure 8A). We previously linked HO-1 urinary excretion to HO-1 kidney expression.10 Interestingly, HO-1 urinary excretion rate was significantly increased in both 4-week-old (P = 0.0195) and 7-week-old Col4a3−/− mice (P = 0.0079) compared with age-matched controls (Figure 8B). HO-1-positive stain was localized mainly to proximal tubules on immunohistochemistry slides (Figure 8C) and was significantly increased in 7-week-old Col4a3−/− mice (Supplemental Figure S1C).

ACE2, angiotensin-converting enzyme 2; Cr, creatinine; KO, knockout; WT, wild-type.
To ascertain whether Ang II and HO-1 are causally linked, we examined intrarenal HO-1 protein expression after treatment with an ACE inhibitor. Indeed, Western blot analyses found significantly decreased intrarenal HO-1 expression after ACE inhibitor treatment (Supplemental Figure S3, A and B). Furthermore, urinary excretion of HO-1 decreased significantly in Col4a3−/− mice treated with the ACE inhibitor (P = 0.0017) (Supplemental Figure S3C).

To further delineate the effect of bioactive peptides of RAS on HO-1 expression, we examined HO-1 expression in PTECs in vitro, in response to Ang II, Ang-(1−7), and an Ang receptor antagonist (losartan). Human primary PTECs were treated with control medium, Ang II, Ang II and Ang (1−7), or Ang II and losartan for 8 hours. HO-1 protein expression was significantly increased in Ang II-treated PTECs compared with control (P = 0.0209) and decreased in the presence of Ang-(1−7) (P = 0.0146) or losartan (P = 0.0231) (Figure 8D).

**Discussion**

Our goal was to better understand the intrarenal RAS in AS. We had the following three main aims: i) to determine the intrarenal expression of RAS components in AS compared with control mice, ii) to examine the intrarenal levels of key bioactive RAS peptides in the context of ACE2 activity, and iii) to assess whether renal expression of previously defined Ang II-induced genes and proteins reflects the balance of bioactive peptides of RAS in AS mice. We studied Col4a3−/− mice, a well-characterized experimental model of human AS, at an age before advanced chronic injury develops. Albuminuria was present in 4-week-old Col4a3−/− mice and progressed in 7-week-old Col4a3−/− mice, accompanied by histologic injury, including glomerulosclerosis and tubulointerstitial fibrosis.

Our first main observation was a marked increase in the renal Ang II level and a decrease in the Ang-(1−7) level in the kidneys of 7-week-old Col4a3−/− mice compared with WT mice, although plasma Ang-(1−7) and Ang II/Ang-(1−7) ratio were not altered. These findings suggested that local Ang peptide processing may play a main role in AS nephropathy. We also found that both renin and AGT mRNA and protein were increased in 7-week-old Col4a3−/− mouse kidneys. Renin is the rate-limiting enzyme for the formation of Ang I, and up-regulation could lead to enhanced Ang I generation. In addition, renin can signal through its own receptor, independently of its enzymatic activity, and this signaling was previously linked to glomerular injury and disease progression.11–13 Similarly, tubular AGT overexpression alone was linked to hypertension and progressive renal injury.14 In PTECs of diabetic mice, increased AGT expression depended on the generation of reactive oxygen species.15,16 Albuminuria is known to increase tubular oxidative stress and may be the cause of increased tubular AGT expression.17,18 More recently, Ichikawa and colleagues19 reported that liver-derived, filtered AGT was the primary source of intrarenal Ang II and contributed to the increase in renal Ang II in mice with impaired glomerular permselectivity. Although filtered AGT may contribute to Ang II formation in Col4a3−/− mice, we also observed increased mRNA expression, suggesting increased local production.

We next observed that ACE expression was decreased in the kidneys of 7-week-old Col4a3−/− mice compared with WT mice, although mean values for ACE activity were similar. These findings suggest that changes in ACE activity, alone, cannot account for the increased tissue Ang II peptide levels in our Col4a3−/− mice.

We then examined the expression and activity of two other enzymes known to be involved in processing of Ang peptides. We measured chymase activity to evaluate whether the increased Ang II level in 7-week-old Col4a3−/− mice depended on chymase activity. Chymase is a chymotrypsin-like serine protease present in the secretory granules of mast cells, but it is also expressed in normal human kidneys.20 Although Ang II formation in the kidney is mainly ACE
Figure 7  Heatmap of mRNA expressions of Ang II-regulated proteins in kidneys of 4- and 7-week-old WT and Col4a3−/− mice. Unsupervised hierarchical cluster analysis of kidney expression of 76 Ang II-regulated genes in WT and Col4a3−/− mice. Gene expression was performed by Affymetrix Gene Chip Mouse Gene version 2.0 ST arrays. Columns represent kidney samples, and rows represent different genes. Red color indicates increased expression relative to mean (white color), whereas blue color indicates decreased expression relative to mean. *Hmox1* is indicated by the black arrow. *n* = 8 arrays per group and at each time point. Ang II, angiotensin II; Col4a3−/−, homozygous for collagen, type IV, α3 gene; *Hmox1*, heme oxygenase-1 gene; KO, knockout; WT, wild-type.
Figure 8 HO-1 analyses in vivo and in vitro. HO-1 protein expression in kidneys of WT and KO mice by Western blot analysis. A: HO-1 protein expression in kidneys is significantly higher in 7-week-old KO mice than in age-matched WT or 4-week-old mice (P = 0.0071). Box-and-whisker plots of HO-1 urine excretion in WT and KO mice. B: HO-1 urine excretion adjusted for Cr in 4- and 7-week-old mice. Immunostaining for HO-1 indicates that HO-1 expression is increased in 7-week-old KO mice compared with age-matched WT or 4-week-old mice. C: HO-1 was present in proximal tubules. HO-1 expression in primary human renal PTECs stimulated with Ang II and Ang-(1-7) in vitro. D: Representative Western blot analysis and densitometry of PTECs stimulated with control, A2, A2+A1-7, or A2+Los for 8 hours. Data are expressed as means ± SEM. n = 6 in the WT group (B); n = 5 in the WT group (B); n = 3 in each group (D). *P < 0.05, **P < 0.01 versus control; P < 0.05 versus Ang II-treated cells. Original magnification, ×100 (C). Ang, angiotensin; A2, Ang II; A2+A1-7, Ang II + Ang-(1-7); A2+Los, Ang II + losartan; Cr, creatinine; HO-1, heme oxygenase-1; KO, knockout; PTEC, proximal tubular epithelial cell; WT, wild-type.

Renal RAS Dysregulation in AS

dependent, a role for chymase was also reported. Chymase expression was faintly detectable in the glomeruli and vascular smooth muscle cells of normal human kidneys, whereas it was markedly up-regulated in kidneys of diabetic patients. Moreover, it was found that mesangial cells in culture express chymase mRNA, and that its expression is increased by high glucose stimulation. Chymase-dependent Ang II formation plays an important role in the development of vascular proliferation in the grafted veins. However, we found chymase activity to be decreased in 7-week-old Col4a3−/− mice compared with age-matched WT mice.

We next focused on ACE2. ACE2 is a monocarboxy peptidase that cleaves Ang I and Ang II to generate Ang-(1-9) and Ang-(1-7), respectively, and is 400-fold more efficient at metabolizing Ang II than Ang I. It plays a significant role in the degradation of Ang II and the generation of Ang-(1-7). ACE2 attenuates the biological effects of Ang II by both reducing Ang II concentrations and increasing Ang-(1-7) concentrations. Thus, ACE2 deletion worsens Ang II-induced hypertension in mice. In addition, we and others reported that ACE2 deletion or pharmacologic blockade accelerated diabetic kidney injury and Ang II-induced kidney inflammation and fibrosis. Moreover, Ang II was able to up-regulate ACE and down-regulate ACE2 in human kidney tubular cells. Consistently, a recent study reported that elevated Ang II levels stimulated ACE2 lysosomal degradation, thereby reducing its expression and activity. Several studies suggest that inhibition of Ang II formation or AT-1R signaling leads to increased ACE2 levels in vivo. ACE2 deletion in mice subjected to unilateral ureteral obstruction results in increased Ang II levels, decreased Ang-(1-7) levels, and exaggerated kidney inflammation and fibrosis. In addition, Ang II increases ACE2 shedding in reactive oxygen species-dependent manner in cardiac tissue, suggesting that a similar mechanism might be operative in kidney tissue. Increased proteinuria might induce proximal tubule reactive oxygen species generation and reactive oxygen species-dependent tumor necrosis factor-α convert enzyme might induce ACE2 shedding, although our work does not support this mechanism on the basis of decreased, rather than increased urinary excretion of ACE2. Thus, decreased ACE2 protein expression and increased Ang II peptide level in the kidney may be associated with proteinuria. To determine whether ACE2 may regulate the expression of these RAS components, we examined Ang II and Ang-(1-7) peptide levels after mrACE2 treatment. mrACE2 treatment partially corrected Ang II and Ang-(1-7) peptide levels in AS nephropathy mice. Therefore, our study suggests that the increased renal Ang II level and decreased Ang-(1-7) level in 7-week-old Col4a3−/− mice were associated with decreased renal ACE2 expression and activity and could be corrected, at least in part, by administration of mrACE2.

Studies have reported that the urinary excretion rate of ACE2 is increased in humans and mice with diabetes. In db/db mice, increased urinary excretion rate parallels kidney ACE2 activity. In accord with the changes in protein expression and ACE2 activity, we found that urinary ACE2
excretion was decreased in our 7-week-old Col4a3<sup>−/−</sup> mice compared with age-matched controls. Taken together these findings suggest that kidney ACE2 expression is reflected in urinary excretion rate.

Ang-(1–7) levels were significantly reduced in 7-week-old Col4a3<sup>−/−</sup> mice compared with WT mice, also in keeping with the low ACE2 expression and activity. Ang-(1–7) has vasodilatory, natriuretic, and antiproliferative actions, and it counterbalances the effects of Ang II. The ratio of Ang II/Ang-(1–7) was significantly increased, suggesting that Ang II-mediated effects would predominate in the kidneys of 7-week-old Col4a3<sup>−/−</sup> mice. The importance of Ang II/Ang-(1–7) ratio was highlighted in previous studies. Our observations suggest that the decrease in ACE2 activity not only contributed to increased Ang II levels but also led to a decline in renal Ang-(1–7) levels and that both of these effects may contribute to progressive kidney injury in this model of AS.

We also found that the main receptors for Ang II and Ang-(1–7), AT-1R and MasR, respectively, were overexpressed in 7-week-old Col4a3<sup>−/−</sup> mice. AT-1R expression was found to be critical for the development of hypertension, and its overexpression may indicate increased activation. MasR gene deletion was associated with loss of glomerular permselectivity. Increased expression of the MasR in Col4a3<sup>−/−</sup> mice could reflect compensation for decreased Ang-(1–7) generation. Accumulating evidence suggests that the balance between the ACE/Ang II/AT-1R versus the ACE2/Ang-(1–7)/MasR axes determines the final output of RAS activity, and increased expression of the receptors might be associated with increased tissue sensitivity to the effector peptides.

Increased renal Ang II peptide level and the loss of the counterbalancing Ang-(1–7) was also reflected in our measures of an Ang II signature that we recently defined in PTECs. Our third main observation was that an Ang II gene signature set was overexpressed in kidneys of 7-week-old Col4a3<sup>−/−</sup> mice. Renal HO-1 protein expression, an important component of the Ang II gene signature, was increased in 7-week-old Col4a3<sup>−/−</sup> mice, and this increase was abolished with ACE inhibition. We have reported that Ang II up-regulates renal HO-1 in an AT-1R–dependent manner and that the increase in kidney expression is reflected in the urinary excretion rate of HO-1. Consistently, the urinary excretion rate of HO-1 was increased in 7- and 4-week-old Col4a3<sup>−/−</sup> mice but dramatically diminished in ACE inhibitor–treated Col4a3<sup>−/−</sup> mice. The urinary excretion rate of HO-1 may represent an early marker of renal injury and RAS dysregulation in the kidney. Moreover, our in vitro studies found that HO-1 expression in PTECs is regulated by both Ang II and Ang-(1–7) and may be AT-1R dependent. This is consistent with our notion that reduced ACE2 expression and activity led to an increase in Ang II and a reduction in Ang-(1–7) levels in the kidneys of the Col4a3<sup>−/−</sup> mice and that both of these effects contributed to the increase in renal expression of Ang II-induced genes.

**Conclusion**

The early phase of kidney injury in mice with experimental AS is associated with marked changes in expression of components of the RAS in the kidney. Although RAS probably does not initiate injury in this model, based on histopathologic injury and proteinuria at 4 weeks of age, it is activated soon after the initial injury and is a significant driver of disease progression. Reduced ACE2 expression and activity contributes to altered Ang peptide levels, including an increase in Ang II and a decrease in Ang-(1–7) kidney levels, likely contributing to progressive renal injury. ACE2 and HO-1 may serve as markers of AS kidney injury, and administration of ACE2 and/or Ang-(1–7) may represent novel therapeutic approaches to AS.
