From the Institutes of Cardiovascular and Cell Sciences* and Infection and Immunity,§ St. George’s University of London, London, United Kingdom; the Fetal Medicine Unit,‖ St. George’s Hospital, London, United Kingdom; and the Experimental and Clinical Research Center,† a Joint Cooperation between the Max-Delbrück Center for Molecular Medicine and the Charité Medical Faculty, Berlin, Germany

The mechanisms of deficient placentation in the first trimester remain poorly understood, although apoptosis, hypoxia, and oxidative stress have been implicated. High uterine artery Doppler resistance indexes (RIs) are predictive of placental complications of pregnancy, such as preeclampsia, fetal growth restriction, and stillbirth. We provide evidence that even in the first trimester, pregnancies with high uterine artery Doppler RI demonstrate alterations in placental gene and protein expression. Apoptosis was significantly higher in high RI placental tissue, as determined by Western blot analysis of cleaved poly (ADP-ribose) polymerase and caspase 3. Protein expression of the trophoblast survival factor insulin-like growth factor-2 was significantly lower. Both high and normal RI placentas showed evidence of hypoxia and oxidative stress with expression of hypoxia-inducible factors 1α and 2α, heat shock protein 70, presence of nitrotyrosine residues, and lipid peroxidation. We observed no exaggerated placental hypoxia or oxidative stress associated with high RI pregnancies. High RI placental tissue demonstrated an altered balance of antioxidant enzyme activity. Hypoxia and oxidative stress appear to be a physiological state in early pregnancy; our data did not support the hypothesis that they are associated with deficient placentation in the first trimester. Higher levels of apoptosis, reduced insulin-like growth factor-2 expression, and altered antioxidant defenses may contribute to abnormal placentation and the later development of pregnancy complications, such as preeclampsia, fetal growth restriction, and stillbirth. (Am J Pathol 2015, 185: 2731–2741; http://dx.doi.org/10.1016/j.ajpath.2015.06.020)

Successful outcome of pregnancy is dependent on placental sufficiency, namely successful implantation and remodeling of the maternal uterine spiral arteries in early pregnancy. Disorders of pregnancy related to deficient placentalization include preeclampsia (PE), fetal growth restriction (FGR), abruption, and stillbirth.1–3 The pathophysiology of these placental obstetric disorders remains unclear, although advances in our understanding have been made in recent years.4,5 PE, in particular, is a major cause of maternal morbidity and mortality worldwide and occurs in 2% to 5% of pregnancies.6 Evidence of oxidative stress, hypoxia, and altered antioxidant defenses have been demonstrated in placental studies of pregnancies affected by PE.7,8 Apoptosis, which may result from increased cell stress, has also been implicated in the pathogenesis of deficient placentation, with higher levels of placental apoptosis in PE and FGR.9,10 However, study of the placenta after delivery has limited value because by that
time the disease process has progressed to the point that delivery is indicated. These studies, although highly suggestive that pathways involving placental hypoxia, oxidative stress, and apoptosis are involved in diseases of placental origin, are unable to answer the question of whether they occur as a response to the disease or are truly causal in the pathogenesis. If we are to institute treatments to ameliorate, or ideally prevent, the consequences of poor placentation, then an understanding of the pathophysiology in the first trimester is necessary.

Uterine artery Doppler (UtAD) ultrasound has been shown to be predictive of placental complications in pregnancy.\(^{11,12}\) It has a greater ability to predict preterm PE and PE associated with FGR than term disease, which may not have such a clear placental origin.\(^{13–15}\) High-resistance UtAD indices in the first trimester are associated with decreased endovascular trophoblast invasion\(^{16}\) and an increased risk of placental complications of pregnancy.\(^{11}\)

We have previously shown functional differences in high-resistance pregnancies in trophoblast sensitivity to apoptotic stimuli and decidual natural killer cell function that would potentially have a detrimental impact on placentation.\(^{17,18}\) We hypothesized that placentas from pregnancies with high-resistance UtAD flow would demonstrate alterations in apoptosis, oxidative stress, antioxidant defenses, and placental oxygen signaling.

**Materials and Methods**

First-Trimester UtAD and Pregnancy Outcome in Continuing Pregnancies

This was a prospective, observational study of women booking routine antenatal care. All women with a singleton pregnancy, attending for routine first-trimester nuchal translucency ultrasound assessment, were offered the option to participate in the study. Written informed consent was obtained from them, and the study was approved by the local ethics committee.

Transabdominal UtAD assessment was performed by the sonographer at the time of the nuchal translucency scan. UtAD indices were measured as described previously.\(^{16}\) In brief, the paracervical vascular plexus was identified and color Doppler was used to identify the uterine artery as it made its ascent to the uterine body. Pulsed-wave Doppler was used to obtain uterine artery waveforms. When three similar consecutive waveforms were obtained, the presence of a protodiastolic notch was recorded and the resistance index (RI) was measured. The RI was preferred to the pulsatility index (PI) in this study because it has demonstrably better intraobserver and interobserver measurement repeatability.\(^{19}\) The patients and their clinicians were blinded to the results of the first-trimester UtAD assessment. Patient characteristics, including demographic details, and obstetric and medical histories were obtained at the first hospital visit and entered into our database. All pregnancy outcomes were obtained from the delivery suite database. Cases with fetal chromosomal or structural abnormalities, intrauterine infection, toxic insult (alcohol or drugs), medication (aspirin, heparin, antioxidants, or steroids), or concurrent maternal disease (eg, renal disease, connective tissue disease, malnutrition, cardiac disease, and diabetes) were excluded from the study. Patients who had a previous pregnancy affected by PE were included in the study; however, according to the exclusion criteria, none was routinely prescribed prophylactic therapy.

FGR was defined as a birth weight <10\(^{th}\) percentile for gestational age (GA) with abnormal Doppler indexes (umbilical artery PI >95\(^{th}\) percentile, middle cerebral artery PI <5th percentile, or ductus venosus PI >95\(^{th}\) percentile for GA). Stillbirth was defined as intrauterine demise after 24 weeks’ gestation. PE was defined after 20 weeks’ gestation, according to the guidelines of the International Society for the Study of Hypertension in Pregnancy. This requires two recordings of diastolic blood pressure of 90 mmHg at least 4 hours apart in previously normotensive women, proteinuria of 300 mg or more in 24 hours, or two readings of at least 2+ on dipstick analysis of midstream or catheter urine specimens if no 24-hour collection is available.\(^{20}\) Pregnancy outcomes from this data set have previously been published in several prospective series.\(^{13,14,21–24}\) However, the results were analyzed with an emphasis on screening performance rather than the positive predictive value for placental complications; we, therefore, present the data with these results.

**Doppler Ultrasound Characterization and Tissue Collection**

Determination of uterine artery RI was performed in women attending a clinic for termination of pregnancy in the first trimester, as previously described,\(^{16}\) at St. George’s Hospital (London, UK). Ethical committee approval and full written consent were obtained (reference, 01.96.8 and 01.78.5). Inclusion criteria were singleton pregnancy, GA of 9 to 14 weeks by crown-rump length (assigned by transvaginal measurement in accordance with local unit clinical policy), normal fetal anatomy, and nuchal translucency with no known maternal medical condition or history of recurrent miscarriage. High-resistance cases were defined as a mean RI >95\(^{th}\) percentile with bilateral diastolic notches. Normal-resistance cases had a mean RI of <95\(^{th}\) percentile. Tissue obtained from first-trimester surgical terminations of pregnancy was collected and rinsed in ice-cold phosphate-buffered saline. Placental villous tissue was separated from the decidua by blunt dissection and was randomly sampled and divided. Approximately 100 mg of tissue was snap frozen in liquid nitrogen in two to three aliquots and stored at \(-70^\circ C\) until use.

**Protein Extraction**

Placental villous tissue (approximately 100 mg) was placed in a lysing tube (Matrix D; MP Biomedicals, Santa Ana,
CA) with 1 mL ice-cold radioimmunoprecipitation assay buffer with protease inhibitors (1 mmol/L phenylmethylsulfonyl fluoride, 60 μg/mL aprotinin, and 1 mmol/L sodium orthovanadate). This was then homogenized (Fast Prep 24; MP Biomed) for two cycles of 30 seconds. The extract was then incubated on ice for 20 minutes and then centrifuged at 4°C at 15,000 \( \times g \) for 15 minutes. The supernatant was then further centrifuged at 4°C at 10,000 \( \times g \) for 10 minutes. Protein estimation was performed on the supernatant by Bradford assay (Sigma-Aldrich, St. Louis, MO).

### Western Blot Analysis

Placental lysates were prepared in Laemmli buffer [50 mmol/L Tris-HCl (pH 6.8), 2% (w/v) SDS, 10% (v/v) glycerol] at 1 mg/mL with 3% (w/v) β-mercaptoethanol and heated to 90°C for 5 minutes. Proteins were separated by SDS-PAGE and transferred to a polyvinylidene difluoride membrane (Hybond-P; Amersham, Buckinghamshire, UK), and Western blot analysis was performed, as previously described, using 1:1000 rabbit anti-BAX (catalog number 2772; Cell Signaling, Danvers, MA), 1:1000 rabbit anti-BCI2 (2872; Cell Signaling), 1:1000 mouse anti-caspase 3 (9668; Cell Signaling), 1:500 rabbit anti-cleaved poly (ADP-ribose) polymerase (G7341; Promega, Fitchburg, WI), 1:1000 rabbit anti-heart shock protein 70 (SPA 812; Enzo Life Sciences, Exeter, UK), 1:1000 mouse anti–heme-oxygenase 1 (ab13248; Abcam, Cambridge, UK), 1:1000 mouse anti–hypoxia-inducible factor (HIF) 1α (610958; BD Transduction, BD Biosciences, Oxford, UK), 1:1000 rabbit anti-HIF2α (NB100-480; Novus Biologicals, Littleton, CO), 1:1000 mouse anti-nitrotyrosine (ab2066; Abcam, Cambridge, UK), 1:5000 mouse anti–insulin-like growth factor (IGF)-1 (ab40789; Abcam), 1:1000 mouse anti-IGF2 (ab63294; Abcam), 1:10,000 rabbit anti-actin (ab2066; Abcam), and 1:10,000 mouse anti-α-tubulin (ab7291; Abcam). The blots were scanned and densitometry was performed using ImageJ software version 1.43u (NIH, Bethesda, MD). Results are expressed as a ratio of protein number 2772; Cell Signaling, Danvers, MA), 1:1000 rabbit anti-BCI2 (2872; Cell Signaling), 1:1000 mouse anti-

### Antioxidant Enzyme Activity and Lipid Peroxidation Assay

Glutathione peroxidase assay (703102; Cayman Chemicals, Ann Arbor, MI), superoxide dismutase (SOD) assay (706002; Cayman Chemicals), and lipid peroxidation assay (437634; Calbiochem, Merck Millipore, Billerica, MA) were performed on 10 to 20 μL of placental lysate, prepared per the manufacturer’s instructions. Final enzyme activity was calculated by correcting for protein concentration, determined by Bradford assay.

### Detection of VEGF-A and Leptin

Total vascular endothelial growth factor (VEGF)-A and leptin were detected in placental lysates using enzyme-linked immunosorbent assay [ELISA; Leptin DY398 Human Duo-Set (R&D Systems Europe, Abingdon, UK) and VEGF-A ELISA 900-K10 (Peprotech, London, UK)], according to the manufacturer’s instructions. Sample concentrations were interpolated from the standard curves and adjusted for protein concentration, determined by Bradford assay.

### Immunohistochemistry

Placental tissue was formalin fixed and paraffin embedded, and sections (10 μm thick) were cut. Slides were dewaxed in xylene for 10 minutes, followed by rehydration through graded ethanol (100% w/v, 95% w/v, 80% w/v, and 70% w/v) for 5 minutes each, with a final wash in water. Antigen retrieval was performed in boiling tris-HCL buffer (10 mmol/L, pH 10) for 10 minutes. Sections were then washed in tris-buffered saline (TBS), permeabilized in TBS/0.2% (v/v) Triton X-100 (Sigma-Aldrich) for 5 minutes, and again washed in TBS. They were then blocked in TBS/10% (v/v) goat serum/1% (w/v) bovine serum albumin for 1 hour at room temperature and again washed with TBS. Mouse anti-human cytokeratin M30 (0.5 μg/mL) or cytokeratin 7 (0.62 μg/mL). After further washes in TBS, the biotinylated and horseradish peroxidase–conjugated secondary antibody was applied for 10 minutes at room temperature (Histofine kit; Invitrogen, ThermoFisher Scientific, Paisley, UK). Sections were incubated with diaminobenzidine (Dako, Ely, UK) for 1 to 5 minutes until positive staining was identified by a brown color under microscopy. Sections were then mounted and visualized, and digital images were stored [IX70 inverted microscope (Olympus, Southend-on-Sea, UK) and C4742-95 digital camera (Hamamatsu Photonics, Welwyn Garden City, UK)]

### TUNEL Staining

Sections were prepared as above, then incubated in permeabilization solution [0.1% (v/v) Triton X-100 and 0.1%
(w/v) sodium citrate] for 8 minutes. Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) staining was performed per manufacturer’s instructions (catalog number 11767305001; Roche, Welwyn Garden City, UK). Sections were visualized by fluorescence microscopy, and digital images were captured as previously described in Immunohistochemistry.

Microarray Analysis

Placental samples from GA-matched pregnancies in high RI and normal RI cases (n = 11) were collected as above. Total mRNA was isolated with a combined protocol of QIAzol lysis reagent and Qiagen RNeasy mini kit (including the RNase-Free DNase set; Qiagen, Manchester, UK), according to the manufacturer’s protocol. RNA quantity and quality were confirmed by RNA 6000 Chip in the 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA) and NanoDrop UV/VIS Spectrometer (PepLab, VWR, Lutterworth, UK). Microarray studies were performed with the Human HT-12_V3.0_R2 (Illumina, San Diego, CA), according to the minimum information about a microarray experiment criteria. Briefly, total RNAs were hybridized to the Illumina array after labeling using the Illumina TotalPrep RNA amplification kit. Illumina GenomeStudio software version 2011.1 with gene expression module version 1.9.0 was used to export probe-level data without normalization or background correction. For analysis, Idat files were imported to GenomeStudio (Illumina), and raw data were exported in text format. Data were analyzed in Gene Spring version 11.5.1 (Agilent Technologies). In brief, data were normalized using quantile normalization and baseline transformed to the median of all control samples. Sample distributions were checked for consistency and conformity to a gaussian distribution by qualitative methods, and replicate consistency was assessed using principal component analysis. Data were filtered to remove unexpressed or unreliable data such that remaining entities should have a detection P > 0.6 in 100% of samples for any one of the two conditions. The most differentially regulated genes were identified by using a fold change of 1.5 filter and t-test with a corrected P < 0.05. Gene ontology analysis was performed using a corrected P < 0.1 to allow a larger gene set for analysis. Gene ontology categories relating to a biological process were determined by Ariadne pathway studio analysis (Elsevier, London, UK) and by AmiGO 2 database entry for each gene (http://amigo.geneontology.org/amigo, last accessed June 1, 2015).26 Microarray data have been submitted to the European Bioinformatics Institute Array Express data repository (http://www.ebi.ac.uk/arrayexpress, accession number E-MTAB-3265).

Statistical Analysis

Data were analyzed with GraphPad Prism version 6 (GraphPad, San Diego, CA). Normal distribution was assessed by Kolmogorov-Smirnov tests. Groups were compared by using a Student’s unpaired t-test and are presented as means ± SEM.

Results

Outcomes in Ongoing Pregnancies with First-Trimester High-Resistance Uterine Artery Blood Flow

In our data set of 9952 ongoing pregnancies, cases with UtAD RI >95th percentile in the first trimester (n = 568) had a 15% risk of PE (86 of 568) compared with a 2.8% risk in cases with UtAD RI <95th percentile (264 of 9384). In all, women with the highest degree of placental resistance had a 24% chance of developing a placental complication of pregnancy (PE, FGR, or stillbirth) compared with women <95th percentile who had a 4.9% risk. Full demographic details are listed in Supplemental Table S1. Pregnancy outcomes from this data set have previously been published in several prospective series;33,34,21,23,27 however, the results were analyzed with an emphasis on screening performance rather than the positive predictive value for placental complications.

Gene Expression Is Altered in Placental Tissue from High RI Pregnancies

Placental gene expression has been shown to be altered at the time of delivery in PE and FGR, particularly in pathways involving inflammation, oxidative stress, and hypoxia.28,29 There is a paucity of data in pregnancies with poor placentation in the first trimester, with two studies from chorionic villous sampling reporting altered gene expression months before the onset of clinical disease.30,31 We, therefore, determined placental gene expression by microarray in GA-matched high RI and normal RI cases. We found that 26 genes were significantly differentially expressed in the high RI versus the normal RI group (>1.5-fold change, P < 0.05); six of these demonstrated up-regulation of expression, whereas the remaining 23 were down-regulated. The genes and their gene ontology are presented in Table 1. Gene ontology analysis identified seven ontologies over-represented in the biological process category; these included immune system response, cell death and apoptosis, response to stress, cyclooxygenase pathway, inflammatory response, and metabolics. Pathways involving hypoxia and oxidative stress did not appear altered (Supplemental Figure S1).

HIF1α Protein Expression Is Reduced in Placental Tissue from High RI Pregnancies

HIF1α and HIF2α are master regulators of the hypoxia response32 and are known to be expressed in the first-trimester placenta.33 Placental hypoxia has been implicated in the pathogenesis of PE, both at the time of disease and in the first trimester,33,34 and increased HIF expression in placenta from pregnancies with PE has been demonstrated.35 We evaluated protein expression of HIF1α and HIF2α in high RI and normal RI placental tissues. Significantly lower levels of HIF1α were found (P = 0.022, n = 17 and 16, respectively) (Figure 1A); however, HIF2α levels were not

**Table 1** Differentially Expressed Genes in High RI Compared with Normal RI Placental Tissue

- **Illumina microarray of gestational age (GA)–matched, first-trimester placental tissue (n = 11).** **GA (in days) for normal, 73.64 ± 5.1; high, 73.82 ± 3.9.** **Gene ontology categories relating to a biological process determined by Ariadne pathway studio analysis and by AmiGO 2 database entry for each gene.**

- **BMP, bone morphogenetic protein; IAP, inhibitor of apoptosis; NLR, nucleotide-binding domain and leucine-rich repeat containing; PAI, plasminogen activator inhibitor; PI-GF, placental growth factor; RI, resistance index.**
different \((P = 0.553, n = 16\) and 15, respectively\) (Figure 1B).

VEGF-A is a known important downstream target of HIF signaling, is abundant in the first-trimester placenta, and has important roles in regulating angiogenesis\(^{36}\). Leptin has been shown to be dysregulated in PE\(^{20}\) and is also a target of HIF signaling. We, therefore, determined the levels of these proteins by ELISA in placental lysate. High RI and normal RI pregnancies did not differ in the level of either total VEGF-A or leptin \((n = 16\) in each group\) (Figure 1, C and D, respectively).

**Placental Tissue in the First Trimester Demonstrates Evidence of Oxidative Stress**

Mild oxidative stress occurs in normal pregnancy,\(^ {37} \) and a burst of oxidative stress occurs at 10 to 12 weeks’ gestation as the fetoplacental unit adapts to an increase in oxygen.\(^ {38, 39} \) The evidence linking oxidative stress and PE is convincing\(^ {37}\); however, the mechanisms of pathogenesis and the timing of the onset of oxidative stress are less well understood. We evaluated several different end points of oxidative stress within placental tissue, including nitrotyrosine residues, lipid peroxidation, and heat shock protein 70 levels. There was evidence of oxidative stress in all samples tested; however, no difference in the level of placental tissue markers of oxidative stress was found in pregnancies with high RIs compared with normal indices (Figure 2, A–C).

**GPx Activity Decreases and SOD Activity Increases in Placental Tissue from High RI Pregnancies**

The expression and activity of antioxidant enzymes increase at 10 to 12 weeks’ gestation, concomitant with the onset of maternal perfusion of the placenta\(^ {40, 41} \); aberrant antioxidant defenses at the time of disease have been implicated in the pathogenesis of PE.\(^ {38, 39} \) We assessed enzyme activity of glutathione peroxidase (GPx) and SOD with the aim of quantifying the functional level of these two important antioxidant systems within the placenta. Significantly lower GPx activity was seen in the placental tissue from high RI pregnancies \((P = 0.007, n = 10\) in each group\) (Figure 2D). In contrast, higher SOD activity was demonstrated in the high RI group \((P = 0.014, n = 8\) and 9 in two groups\) (Figure 2E).

**Apoptosis Increases and IGF2 Protein Expression Decreases in Placental Tissue from High RI Pregnancies**

We have previously shown that first-trimester extravillous trophoblasts from high RI pregnancies are more sensitive to apoptotic stimuli,\(^ {37} \) and higher levels of placental apoptosis have been shown in pregnancies with PE and FGR.\(^ {38, 40} \) We, therefore, investigated markers of placental apoptosis in high RI and normal RI placentas by Western blot analysis. High RI cases had significantly higher levels of cleaved caspase 3 \((P = 0.0002, n = 16\) in each group\) (Figure 3A).

**Figure 1**

Hypoxia-inducible factor (HIF), total vascular endothelial growth factor (VEGF)-A, and leptin protein expression in placental lysate from high resistance index (RI) and normal RI pregnancies. A: HIF1α expression determined by Western blot analysis of high RI and normal RI placental lysate for HIF1α (120 kDa), with tubulin (55 kDa) detected as loading control, is significantly lower in high RI cases \((P = 0.022)\). Gestational age (GA; in days) for normal, 79.44 ± 2.5; high, 82.81 ± 2.7. C: Leptin protein expression, determined by enzyme-linked immunosorbent assay (ELISA) in high RI and normal RI placental lysate for HIF2α (120 kDa), with tubulin (55 kDa) detected as loading control, is not different between the two groups \((P = 0.553)\). Ga (in days) for normal, 75.06 ± 2.5; high, 82.81 ± 2.7. D: Total VEGF-A protein expression determined by ELISA and expressed as ng/mg protein concentration, shows no significant difference \((P = 0.186)\). Ga (in days) for normal, 82.81 ± 2.7; high, 74.54 ± 3.07. *: Total VEGF-A and leptin protein expression decreases and GPx activity increases with high RI pregnancies. \(P = 0.0167, n = 16\) in each group\) (Figure 3B).

Immunohistochemical analysis confirmed apoptosis by TUNEL and CkM30 staining (Figure 4, A–F). We performed a protein array on pooled lysate \((n = 8\) in each group\) (Supplemental Table S2) to provide candidates for further investigation of apoptotic pathways. The array data suggested down-regulation of IGF2; therefore, we investigated it in placental lysates from individual patients. Significantly lower levels of IGF2 were detected in high RI pregnancies \((P = 0.04, n = 16\) in each group\) (Figure 5B); however, no significant differences in IGF1 were seen \((n = 16\) in each group\) (Figure 5A). Placental studies in PE and FGR have suggested alterations in intrinsic mitochondrial regulation of apoptosis.\(^ {42} \) We, therefore, investigated placental Bax and Bcl-2 expression (proapoptotic and antiapoptotic, respectively), with no difference seen between high RI and normal RI tissues (Bax, \(n = 11\) and 12; Bcl-2, \(n = 16\) in each group\) (Figure 5, C and D).
Figure 2  Expression of markers of oxidative stress and antioxidant enzyme activity in placental lysate from high resistance index (RI) and normal RI pregnancies. **A:** Nitrotyrosine expression. Nitrotyrosine/tubulin ratio by densitometry. Immunoblotting of high RI, and normal RI placental lysate loaded onto polyvinylidene difluoride (PVDF) membrane by slot blot matrix, shows no difference (P = 0.95). **B:** Lipid peroxidation measured by 4-hydroxynonenal (4 HNE) and malondiadehyde (MDA) assay, shows no difference (P = 0.59). **C:** Heat shock protein (HSP) 70 expression determined by Western blot analysis of high RI and normal RI placental lysate for HSP 70 (70 kDa), with tubulin (55 kDa) detected as loading control, shows no difference (P = 0.689). **D:** Glutathione peroxidase (GPx) activity measured by assay (703102; Cayman Chemicals). GPx enzyme activity significantly reduces in high RI cases (P = 0.007). **E:** Superoxide dismutase (SOD) activity measured by assay (number 706002; Cayman Chemicals). SOD enzyme activity is higher in high RI cases (P = 0.014). *P < 0.05, **P < 0.01.

**Discussion**

Investigating the pathogenesis of the clinical consequences of poor placentation, such as FGR, PE, and stillbirth, has traditionally been hampered by our inability to study these pregnancies in the first trimester when the critical events for successful placentation development occur. Interventions have, to date, also been disappointing, with aspirin providing only modest benefit and delivery remaining the only cure. It is likely that future interventions will need to start early in pregnancy, long before the clinical consequences become evident, and a fundamental understanding of the mechanisms that determine both sufficient and insufficient placentation is required. We have used the ability to assess impedance to uterine artery flow in the first trimester to study those pregnancies with the highest resistance to flow in comparison to those with normal parameters.

**Oxygen Signaling**

The first-trimester placenta is known to develop in a low oxygen environment, with oxygen levels of 20 mmHg at 8 weeks’ gestation, increasing to >50 mmHg at 12 weeks, concomitant with the onset of maternal arterial perfusion. The association between placental oxidative stress and PE in later pregnancy is well established, although it remains unclear whether hypoxia or reperfusion is causal of this, with a paucity of in vivo data on placental oxygenation in complicated pregnancy. Early hypoxia in the first-trimester placenta has been implicated in the pathogenesis of PE and placental insufficiency, although this theory and a causal role for placental hypoxia have been challenged. There was no evidence in our gene expression data of an up-regulation of hypoxia or oxidative stress genes in placental tissue from pregnancies with high-resistance flow. Consistent with our findings, two previous studies using stored placental samples from chorionic villous sampling of women who subsequently developed PE have also demonstrated no evidence of an increased hypoxic or oxidative stress response in first-trimester placental gene expression. HIF1α is broken down rapidly in conditions of normoxia, and its levels are directly related to the degree of cellular hypoxia. We found significantly lower levels of HIF1α in high RI pregnancies that may be a direct reflection of higher levels of oxygen in vivo. This paradoxically higher level of oxygen may result from deficient plugging of the spiral arteries by extravillous trophoblast and premature perfusion of the placenta by maternal blood, a process that has also been implicated in early pregnancy failure. Oxygen-independent regulation is also important; inflammatory mediators, cytokines, growth factors, and the renin-angiotensin system have been reported to regulate HIF1α and are abundant in
the first-trimester placenta. Our microarray data provide evidence of an altered inflammatory environment in high RI pregnancies with the most differentially regulated genes, including PTGS2 (cyclooxygenase 2), and several CCL3 and CCL4 chemokines. Lower levels of HIF1α may represent a response to an aberrant placental inflammatory environment, and further investigation of these inflammatory markers and of the activation state of fetal villous macrophages would be of interest. We have also shown aberrant chemokine and cytokine production by decidual natural killer cells from high RI pregnancies, suggesting that alterations in the inflammatory microenvironment may extend across the maternal-fetal interface in high RI pregnancies.

We observed no difference in HIF2α levels, suggesting that mechanisms specific to HIF1α may be involved. Although the localization and temporal expression of both HIF1α and HIF2α have been studied in the human placenta, the complexity of their regulation remains poorly understood in comparison to their behavior in other tissue types and human cancer. Alterations in the relative balance between HIF1α and HIF2α in other human tissue have been reported to have effects on cell proliferation, invasion, and angiogenesis, processes also important in placentation. The functional effects in the human placenta remain to be elucidated.

IGF2, which is a known HIF1α-specific target, was down-regulated at a protein level; however, total VEGF-A and leptin were not. HIF1α and HIF2α are known to act on >100 target genes via the hypoxia response element, and redundancy in signaling may reduce a downstream effect in addition, the expression of these proteins is controlled by many intersecting pathways beyond the HIF pathway alone. Villous tissue is a complex mix of several trophoblast types, fetal stromal cells, macrophages, and endothelial cells. Absence of changes in a particular pathway could simply be because of a dilutio

Oxidative Stress and Antioxidant Defenses

There was evidence of oxidative stress in all first-trimester placental tissue studied using a variety of tissue markers;

Figure 5  Expression of regulators of apoptosis in placental lysate from high resistance index (RI) and normal RI pregnancies. A: Insulin-like growth factor (IGF)-1 protein expression determined by Western blot analysis of high RI and normal RI placental lysate for IGF1 (20 kDa), with tubulin (55 kDa) detected as loading control, is not significantly different (P = 0.355). Gestational age (GA; in days) for normal, 79.31 ± 2.3; high, 74.33 ± 2.6. B: IGF2 protein expression, determined by Western blot analysis for IGF2 (50 kDa) with actin (36 kDa), detected as loading control, is significantly reduced in high RI cases (P = 0.040). GA (in days) for normal, 80.94 ± 2.4; high, 77.13 ± 2.5. C: Bax protein expression, determined by Western blot analysis for Bax (20 kDa), with tubulin (55 kDa) detected as loading control. Bax was not significantly different (P = 0.5287). GA (in days) for normal, 75.81 ± 2.7; high, 78.50 ± 2.6. D: Bcl-2 protein expression, determined by Western blot analysis for Bcl-2 (28 kDa), with tubulin (55 kDa) detected as loading control. Bcl-2 is not significantly different between two groups (P = 0.0722). GA (in days) for normal, 80.25 ± 2.5; high, 75.3 ± 2.7. Scatter plot: each point represents an individual patient sample. Data are presented as means ± SEM (statistical analysis t-test). n = 16 (A, B, and D, high and normal RI); n = 11 (C, high RI); n = 12 (C, normal RI). *P < 0.05.

however, placental tissues from high RI and normal RI pregnancies did not differ in their level of oxidative stress markers. Antioxidant defense systems become active in the first trimester with increasing levels of GPx and SOD correlated with both GA and intervillous oxygen levels. High RI placental lysate had significantly lower levels of GPx activity and higher levels of SOD activity. An imbalance in placental antioxidant enzymes may ultimately result in oxidative stress in later pregnancy, even though no effect was seen in the first trimester. PE has been associated with reduced antioxidant enzyme activity. Other human tissue inflammatory mediators, in particular tumor necrosis factor α, have been reported to up-regulate SOD activity. SOD activity in high RI cases may be up-regulated in response to deficient GPx activity. The underlying mechanisms leading to an altered antioxidant balance in the first trimester require further investigation.

Apoptosis and IGF2

Apoptosis is a highly regulated energy-dependent process that is initiated as a response to several different cell stresses, including hypoxia, oxidative stress, and inflammation. There is strong evidence to support increased placental apoptosis in obstetric complications of poor placentaion, including PE and FGR. We found higher levels of apoptotic markers in the placenta from high RI pregnancies. We have previously demonstrated an increased sensitivity of primary trophoblasts from high RI pregnancies to apoptotic stimuli in vitro, and our findings confirm an in vivo effect. Trophoblasts from pregnancies affected by FGR or PE have also been shown to have increased sensitivity to apoptotic stimuli. Higher levels of apoptosis in the first trimester may lead to aberrant development of the villous architecture and fetal vasculature. It is known that fetuses affected by FGR have abnormal placental vessels and smaller placental mass, with the possible consequence of reduced nutrient and oxygen uptake.

We found significantly lower levels of IGF2 in high RI placentas, which may potentially result in increased levels of apoptosis. In a first-trimester explant model, IGF2 has been shown to regulate the trophoblast cell cycle and protect against apoptosis. Apoptosis is considered to play a role in normal placental physiology, particularly in cytotrophoblast cell cycle control and the formation and maintenance of the integrity of the syncytiotrophoblast layer. IGF2 has effects on cell proliferation and invasion; lower levels of IGF2 may conceivably reduce cell proliferation, placental mass, and trophoblast invasion in addition to increasing apoptosis. In the murine placenta, a regulatory effect of IGF2 has been demonstrated on HIF expression, with complex interactions between IGF2, oxygen, and HIF on murine trophoblast proliferation, migration, and invasion. However, this has not as yet been studied in the human placenta.

It is not possible to determine the individual cell types affected from placental lysate; we, therefore, investigated this immunohistochemically by staining for TUNEL, cytokeratin M30, and cytokeratin 7, confirming apoptosis in the trophoblast, with apparent localization to the syncytiotrophoblast. Conflicting results have previously been published as to the site of apoptotic changes seen in both normal and pathological pregnancy, and more recent evidence highlights the difficulty of attributing cell lineage in the first-trimester placenta with evidence that the cytotrophoblast may interdigitate into the syncytiotrophoblast layer.

Conclusions

We provide evidence that first-trimester pregnancies with high RI have differentially regulated placental gene expression, higher placental levels of apoptosis, and lower levels of IGF2 compared with normal RI pregnancies. These changes are apparent several months before the clinical consequences of placental insufficiency become evident. Alterations in antioxidant defense systems and lower placental levels of HIF1α are also seen, which may be because of oxygen-independent regulation as no evidence of differential hypoxia-related gene expression or exaggerated
tissue oxidative stress was found in the first trimester. It is certainly possible that alterations in placental antioxidant balance may lead to increased placental oxidative stress in later pregnancy. Our data support the concept that in the first trimester, low oxygen levels and mild oxidative stress are a normal physiological state and may be important for many aspects of successful placental development. Neither hypoxia nor oxidative stress seem to be associated with poor placental development. Neither hypertension nor oxidative stress seem to be associated with poor aspects of successful placental development. Neither hypertension nor oxidative stress seem to be associated with poor aspects of successful placental development.
