Myocardial Galectin-3 Expression Is Associated with Remodeling of the Pressure-Overloaded Heart and May Delay the Hypertrophic Response without Affecting Survival, Dysfunction, and Cardiac Fibrosis

The β-galactoside—binding animal lectin galectin-3 is predominantly expressed by activated macrophages and is a promising biomarker for patients with heart failure. Galectin-3 regulates inflammatory and fibrotic responses; however, its role in cardiac remodeling remains unclear. We hypothesized that galectin-3 may be up-regulated in the pressure-overloaded myocardium and regulate hypertrophy and fibrosis. In normal mouse myocardium, galectin-3 was constitutively expressed in macrophages and was localized in atrial but not ventricular cardiomyocytes. In a mouse model of transverse aortic constriction, galectin-3 expression was markedly up-regulated in the pressure-overloaded myocardium. Early up-regulation of galectin-3 was localized in subpopulations of macrophages and myofibroblasts; however, after 7 to 28 days of transverse aortic constriction, a subset of cardiomyocytes in fibrotic areas contained large amounts of galectin-3. In vitro, cytokine stimulation suppressed galectin-3 synthesis by macrophages and cardiac fibroblasts. Correlation studies revealed that cardiomyocyte-specific galectin-3 localization was associated with adverse remodeling and dysfunction. Galectin-3 knockout mice exhibited accelerated cardiac hypertrophy after 7 days of pressure overload, whereas female galectin-3 knockouts had delayed dilation after 28 days of transverse aortic constriction. However, galectin-3 loss did not affect survival, systolic and diastolic dysfunction, cardiac fibrosis, and cardiomyocyte hypertrophy in the pressure-overloaded heart. Despite its potential role as a prognostic biomarker, galectin-3 is not a critical modulator of cardiac fibrosis but may delay the hypertrophic response. (Am J Pathol 2016, 186: 1114–1127; http://dx.doi.org/10.1016/j.ajpath.2015.12.017)

Galectin-3, a member of the galectin family, is a 30-kDa β-galactoside—binding lectin with a broad repertoire of cellular functions. Although often viewed as a specific marker for macrophages,1,2 galectin-3 can also be expressed by other cell types on activation, including epithelial cells,3 fibroblasts,4 eosinophils,5 and endothelial cells.6 Galectin-3 exerts a wide range of actions, modulating proliferation, survival, differentiation, and gene expression in many different cell types. The promiscuous subcellular localization of galectin-3 may account for its functional flexibility and explain its diverse and context-dependent in vivo actions. Galectin-3 can be localized in the cytoplasm, cell surface, or the nucleus, or it can be secreted and incorporated into the extracellular matrix7 that modulates cell behavior both through intracellular effects on signaling cascades and through matricellular actions.

Extensive in vitro and in vivo evidence implicates galectin-3 in tissue inflammation and fibrosis. Intracellular galectin-3 plays a critical role in regulating phagocytotic...
activity in macrophages and drives alternative macrophage activation.8 In vivo studies have produced conflicting results, suggesting that galectin-3 expression may mediate both proinflammatory9 and anti-inflammatory actions.10 Profibrotic effects of galectin-3 have been documented in experimental models of hepatic, renal, and vascular fibrosis11–13 and may be mediated through galectin-3–induced acquisition of a fibrogenic macrophage phenotype9 or by direct actions of secreted galectin-3 on fibroblasts.14 A growing body of evidence suggests a role for members of the galectin family in cardiovascular disease.15,16 Over the past decade, clinical studies have documented marked elevations of circulating galectin-3 concentrations in patients with heart failure17 and have generated significant interest in the role of galectin-3 as a biomarker. In patients with acute or chronic heart failure, plasma galectin-3 concentrations were shown to predict mortality and adverse outcome in a variety of clinical settings.18–20 Despite the growing interest in the role of galectin-3 as a circulating biomarker, little is known about the mechanisms of galectin-3 regulation in the failing heart and its potential role in the pathogenesis of heart failure.16 In a transgenic rat model of cardiac hypertrophy, galectin-3 expression was predominantly localized in activated cardiac macrophages and identified animals prone to develop heart failure.21 Moreover, studies in rodent models of cardiac remodeling showed that galectin-3 loss reduces fibrosis, attenuating myocardial dysfunction.22,23 On the basis of these studies, it has been suggested that galectin-3 may be a promising therapeutic target in patients with heart failure. However, both investigations were limited to male animals.

Considering the emerging interest in the role of galectin-3 in heart failure, we designed a systematic investigation of the effects of galectin-3 on cardiac remodeling, using both male and female mice subjected to standardized pressure overload protocols. Our findings suggest that galectin-3 is markedly up-regulated in the pressure-overloaded myocardium, and its expression is associated with active cardiac remodeling. However, despite its potential role as a biomarker, galectin-3 did not affect survival, systolic and diastolic dysfunction, and fibrosis in the pressure-overloaded heart. Genetic loss of galectin-3 had relatively subtle and transient effects on the remodeling myocardium, accelerating hypertrophy and delaying dilation in female animals.

**Materials and Methods**

**Animal Protocols**

Animal experiments were conducted in accordance with the NIH Guide for the Care and Use of Laboratory Animals24 and were approved by the Albert Einstein College of Medicine Institutional Review Boards. Male and female, 2- to 4-month-old wild-type (WT; n = 50) and galectin-3 knockout (KO; n = 46) mice in a C57/BL6 background were purchased from The Jackson Laboratory (Bar Harbor, ME). Mice were anesthetized with inhaled isoflurane. Aortic banding was achieved by creating a constriction between the right innominate and left carotid arteries as previously described.25,26 The degree of pressure overload was assessed by measuring right-to-left carotid artery flow velocity ratio after constricting the transverse aorta. At the end of the experiment, the heart was excised, fixed in zinc-formalin, and embedded in paraffin for histologic studies. Hearts used for histologic analysis were sectioned from base to apex at 250-μm intervals. Mice used for histology underwent 28 days of banding (n = 10 mice per group). As a control, a sham operation without aortic constriction was performed on age-matched mice (n = 4 per group). To study galectin-3 localization in normal mouse tissues, four additional WT mice (4 months of age) were sacrificed. The spleen, liver, kidney, bowel, lung, and heart were harvested, fixed in zinc-formalin, and embedded in paraffin. Additional groups of male and female WT and galectin-3 KO mice underwent transverse aortic constriction (TAC) protocols for 56 days (WT, n = 20; KO, n = 16).

**Echocardiography**

Short-axis M-mode echocardiography was performed before instrumentation and after 7 or 28 days of TAC with the use of the Vevo 770 system (VisualSonics, Toronto, ON, Canada) as previously described.25–27 The following variables were measured as indicators of function and remodeling: left ventricular (LF) end-diastolic diameter, LF end-systolic diameter, LV end-diastolic volume (LVEDV), LV end-systolic volume, ejection fraction, and LV mass. Mice enrolled in the 56-day TAC study had echocardiography at baseline and after 7, 28, and 56 days of TAC. The percentage of change for these variables was calculated for every time point studied with the use of the following formula:

\[
\Delta \text{LVEDV7d} = (\text{LVEDV7d} - \text{LVEDVpre}) \times 100/\text{LVEDVpre}\]

**Doppler Echocardiography and Tissue Doppler Imaging**

Mice undergoing 56-day TAC protocols had Doppler echocardiography and tissue Doppler imaging at baseline and after 7, 28, and 56 days of TAC with the use of the Vevo 2100 system (VisualSonics). Transmural LV inflow velocities were measured from apical four-chamber view by pulsed-wave Doppler. Peak early E (E-wave) and late A (A-wave) filling velocities and E/A ratio were measured according to the guidelines of the American Society of Echocardiography.28 Tissue Doppler imaging of the mitral annulus was obtained from the apical four-chamber view. A 1.0-mm sample volume was placed sequentially at the medial mitral annulus. Analysis was performed for systolic velocity and for the early (E0) and late diastolic velocity (A0). The mitral inflow E velocity to tissue Doppler E’ wave velocity ratio (E/E’) and tissue Doppler early E’ velocity to tissue Doppler late A’ velocity ratio were...
calculated. All Doppler spectra were recorded for three to five cardiac cycles at a sweep speed of 100 mm/second. The color Doppler preset was at a Nyquist limit of 0.44 m/second. The off-line analysis was performed by a sonographer (I.R.) blinded to study groups.

Immunohistochemistry, Dual Immunofluorescence, and Quantitative Histology

To study galectin-3 localization, histologic sections were stained immunohistochemically with a rat anti-mouse galectin-3 antibody (Mac2; dilution 1:200; Cedarlane Laboratories, Burlington, ON, Canada) as previously described.26 Staining was performed with the use of a peroxidase-based technique with the Vectastain ELITE rat kit (Vector Laboratories Inc., Burlingame, CA). Sections were pretreated with a solution of 3% hydrogen peroxide to inhibit endogenous peroxidase activity and incubated with 2% rabbit serum (Vectastain ELITE kit; Vector Laboratories Inc.) to block nonspecific protein binding. Peroxidase activity was detected with diaminobenzidine with nickel. Negative controls were performed with omission of the primary antibody. Tissues from galectin-3 KO mice were used as additional negative controls for Mac2 immunohistochemistry. Slides were counterstained with eosin. Immunofluorescence staining was performed with the use of the following antibodies: rat anti-mouse Mac-2 antibody, anti-α-smooth muscle actin (α-SMA) antibody (dilution 1:200; Sigma-Aldrich, St. Louis, MO), rabbit anti-CD68 antibody (dilution 1:200; Abcam, Cambridge, MA), and rabbit anti-pancytokeratin antibody (dilution 1:250; Bios, Woburn, MA). Cardiomyocytes were outlined with wheat germ agglutinin (WGA) histochemistry, as previously described with an Alexa Fluor 594 Conjugate (dilution 1:500; Life Technologies, Carlsbad, CA). For studies that examined the cellular localization of galectin-3, dual immunofluorescence that combined Mac-2/CD-68, and Mac-2/WGA staining was performed. Myofibroblasts were identified as spindle-shaped α-SMA+ cells located outside the vascular media. Quantitative assessment of the density of galectin-3—expressing myofibroblasts, macrophages, and cardiomyocytes was performed by counting the number of cells that exhibited dual fluorescence in five random fields from two different sections from each heart with the use of Image-Pro Plus software version 4.5.0.29 (Media Cybernetics, Rockville, MD). Cell density was expressed as cells/mm2. Quantitative histology was performed by an investigator (O.F.) blinded to the genotype of the animal, to the time point studied, and to the corresponding echocardiographic data.

Collagen Staining and Assessment of Cardiomyocyte Size

Collagen staining was performed with Sirius Red as previously described.29 The collagen-stained area was quantitatively assessed with Image Pro Plus software and expressed as a percentage of the total myocardial area. Assessment of cardiomyocyte size was performed by measuring the area of 25 random cardiomyocytes, cut in cross-section, from five different regions of slides stained for WGA staining. Cardiomyocyte area was expressed in μm2.

Isolation and Stimulation of Mouse Cardiac Fibroblasts in Collagen Pads

Expression of galectin-3 was studied in cardiac fibroblasts cultured in collagen pads as previously described.29–31 Collagen matrix was prepared by diluting a stock solution of rat 3 mg/mL collagen I (GIBCO Invitrogen Corporation, Carlsbad, CA) with 2× Dulbecco’s modified Eagle’s medium and distilled water for a final concentration of 1 mg/mL collagen. Cardiac fibroblast cell suspensions were mixed with collagen solution to achieve the final concentration of 3 × 105 cells/mL. Subsequently, 500 μL of this suspension was divided into aliquots in a 24-well culture plate (BD Falcon, San Jose, CA) and allowed to polymerize at 37°C for 15 minutes. After polymerization, pads were released from wells, transferred to 6-well culture plate (BD Falcon), and cultured in 1× Dulbecco’s modified Eagle’s medium for 24 hours in the presence or absence of transforming growth factor (TGF)-β1 or IL-1β. After 24 hours the pads were fixed in formalin and embedded in paraffin for immunohistochemical staining. Dual staining for the fibroblast marker transcription factor 21 (Tcf21; dilution 1:100; using a rabbit anti-Tcf21 antibody from Abcam, Cambridge, UK) and galectin-3 was used to identify galectin-3—expressing fibroblasts. The number of galectin-3+ fibroblasts was quantitatively assessed with Image Pro software.

Sorting, Isolation, and Stimulation of Mouse Splenic Macrophages

To examine the effects of cytokines on expression of galectin-3 by macrophages, CD11b+ macrophages were isolated from the mouse spleen with the use of immunomagnetic sorting as previously described.32 The cells were stimulated with IL-1β and TGF-β1 (R&D Systems, Minneapolis, MN) for 4 hours. At the end of the experiment, cells were harvested for RNA extraction. To examine whether the effects of TGF-β1 were mediated through Smad3, galectin-3 expression was compared between macrophages harvested from WT and Smad3 KO mice (from our own colony).33,34

RNA Extraction and qPCR

Total RNA isolated from macrophages was reverse transcribed to cDNA with the use of iScript cDNA synthesis kit (Bio-Rad Laboratories, Hercules, CA) according to the manufacturer’s guidelines. Quantitative real-time PCR (qPCR) was performed with the SsoFast EvaGreen supermix (Bio-Rad Laboratories) method on the iQ5 Real-Time PCR Detection System (Bio-Rad Laboratories) for 40 cycles...
at an annealing temperature (T\Delta\text{Opt} °C) specific for a primer pair. Primers were synthesized with Beacon designer from Premier Biosoft version 8.02 (Palo Alto, CA). Each sample was run in triplicate. The cycle threshold method with the use of GAPDH as the reference gene was used for relative quantification of galectin-3 expression. The following sets of primers were used: galectin-3: forward, 5'-CCTTCTTGTAAGACATCCATT-3' and reverse, 5'-ACGAGCAGTCCAAGATT-3'; GAPDH: forward, 5'-AACGACCCCTT-CATTGACCT-3' and reverse, 5'-CACCAGTAGACTCCA-CGACA-3'.

Statistical Analysis

Data are expressed as means ± SEM. For comparisons of two groups unpaired, two-tailed Student's t-test with the use of (when appropriate) Welch's correction for unequal variances was performed. The U test was used for comparisons between two groups that did not show Gaussian distribution. Mortality was compared with the log-rank test. Associations between echocardiographic and histologic end points were studied with Pearson’s correlation analysis. Data are expressed as means ± SEM. Statistical significance was set at 0.05.

Results

Galectin-3 Expression in Normal Mouse Tissues

We used immunohistochemistry to study galectin-3 localization in normal mouse tissues. The specificity of the Mac2 antibody for galectin-3 was validated in experiments with the use of lung tissue from WT and galectin-3 KO mice (Supplemental Figure S1, A–C). Although often considered a relatively specific marker of macrophages, galectin-3 is expressed by nonmacrophage populations in several organs. In the spleen (Figure 1A), liver (Figure 1B), and kidney (Figure 1C), galectin-3 was predominantly expressed by cells with macrophage morphology. Dual immunofluorescence for the anti—galectin-3 antibody Mac2 and CD68 localizes galectin-3 in liver (C–E) and spleen (F–H) macrophages (white arrows). I and J: However, in the bowel, galectin-3 staining also localizes in epithelial cells of the bowel lumen (I, arrows) and the serosa (J, arrows). Arrowheads show galectin-3+ cells with macrophage morphology in the bowel connective tissue. K: In the kidney, galectin-3 staining is noted in tubular epithelial cells (arrows). L–O: Serial section staining of sections from the mouse kidney (L and M) and bowel (N and O), localize galectin-3 immunoreactivity (L and N, arrows) in pancytokeratin+ epithelial cells (M and O, arrows). Counterstained with eosin. Scale bar = 60 μm.
positive for galectin-3 (Figure 1, I and J). In the kidney, epithelial cells lining the distal convoluted tubules and collecting ducts in the cortex and the thick loops of Henle expressed large amounts of galectin-3 (Figure 1K). Serial section staining for pancytokeratin and Mac-2 localized galectin-3 in epithelial cells in the mouse kidney (Figure 1, L and M) and in the bowel (Figure 1, N and O).

Galectin-3 Expression Is Markedly Up-Regulated in the Pressure-Overloaded Myocardium and Is Localized in Both Cardiomyocytes and Noncardiomyocytes

In the normal mouse LV myocardium, galectin-3 was localized in a small number of interstitial cells with morphologic characteristics of macrophages (Figure 2A). Normal ventricular cardiomyocytes and vascular cells did not express galectin-3. In contrast, in the normal atrium, most atrial cardiomyocytes exhibited galectin-3 immunoreactivity (Figure 2B).

With the use of Mac2 immunohistochemistry we studied the time course and cellular localization of galectin-3 expression in the pressure-overloaded myocardium. The density of galectin-3+ cells markedly increased after 7 and 28 days of TAC ($P < 0.01$ versus control) (Figure 2C). Remodeling of the pressure-overloaded heart was associated with profound changes in cellular localization of galectin-3. After 3 days of TAC, galectin-3 expression in the left ventricle was predominantly localized in interstitial cells with morphologic characteristics of macrophages (arrows). After 7 to 28 days of TAC, intense galectin-3 staining also localizes in a subset of cardiomyocytes adjacent to areas of fibrosis (arrows). A section from a galectin-3 null animal after 28 days of TAC serves as a negative control, showing no galectin-3 staining, thus indicating the specificity of Mac2 immunohistochemistry for galectin-3 (Figure 2D). However, after 7 to 28 days of TAC, a subset of cardiomyocytes, located in areas of fibrosis, exhibited high cytoplasmic immunoreactivity for galectin-3 (Figure 2, E and F). The specificity of Mac2 immunohistochemistry for detection and localization of galectin-3 was confirmed by the absence of immunoreactivity in sections from pressure-overloaded galectin-3 null mice (Figure 2G). In the left atrium, cardiomyocytes exhibited increased galectin-3 staining after 3 to 28 days of TAC (Figure 2, H–J). Atrial tissue from pressure-overloaded galectin-3 null mice exhibited no staining (Figure 2K), serving as a negative control.

Infiltration of the Pressure-Overloaded Myocardium with Galectin-3+ Macrophages and Myofibroblasts

To determine the cellular identity of galectin-3+ cells in the pressure-overloaded ventricle, we used dual immunofluorescence staining. Galectin-3—expressing macrophages...
were identified with dual staining for Mac2 and the macrophage marker CD68. Density of galectin-3⁺ macrophages in the pressure-overloaded myocardium markedly increased after 7 to 28 days of TAC (Figure 3, A–E). Myofibroblasts were identified in the pressure-overloaded myocardium as α-SMA—expressing interstitial cells, located outside the vascular media. The specificity of the α-SMA antibody was validated with appropriate positive and negative controls (Supplemental Figure S1, F–I). The number of galectin-3⁺ myofibroblasts that infiltrated the pressure-overloaded myocardium markedly increased after 7 days of TAC (Figure 3, F–J).

**IL-1β and Activation of TGF-β/Smad3 Signaling Suppress Galectin-3 Synthesis in Isolated Mouse Macrophages**

Macrophages are an important source of galectin-3. Accordingly, we examined whether the cytokines IL-1β and TGF-β1, both prominently involved in cardiac remodeling, 35,36 regulate galectin-3 synthesis in isolated mouse macrophages. Isolated splenic mouse macrophages exhibited high levels of galectin-3 mRNA expression. IL-1β and TGF-β1 stimulation significantly reduced galectin-3 synthesis (Figure 4A). The down-modulatory effects of IL-1β and TGF-β1 were abrogated in Smad3 null macrophages, suggesting that regulation of galectin-3 synthesis in macrophages involved canonical Smad-dependent signaling. Because IL-1β does not directly activate Smad3 signaling, the Smad-dependent effects of IL-1 may reflect indirect actions, mediated through induction of members of the TGF-β family.

**A Subset of Cardiac Fibroblasts Expresses Galectin-3**

Because a subset of myofibroblasts that infiltrated the remodeling heart expressed galectin-3, we examined whether cytokines regulate galectin-3 synthesis in isolated mouse cardiac fibroblasts cultured in collagen pads. Tcf21 staining was used to identify fibroblasts. Approximately 10% of unstimulated Tcf21⁺ fibroblasts exhibited galectin-3 expression (Figure 4, B and C). IL-1β stimulation reduced the absolute number of galectin3⁺ fibroblasts (Figure 4, B–E); however, TGF-β1 stimulation had no effect on the absolute number, or the percentage, of galectin3⁺ cells (Figure 4, B–F).

**In the Pressure-Overloaded Myocardium, Galectin-3 Is Localized in a Subset of Cardiomyocytes**

To identify and quantitate galectin-3⁺ cardiomyocytes, we performed dual immunofluorescence staining for WGA lectin and galectin-3. In normal left atrium, cardiomyocytes exhibited baseline galectin-3 immunoreactivity (Figure 5A) that markedly increased after 7 to 28 days of TAC (Figure 5, B and C). An atrial sample from a galectin-3 KO heart after 28 days of TAC serves as a negative control (Figure 5D). In normal mouse left ventricle, cardiomyocytes did not express galectin-3.
After 7 to 28 days of TAC a significant number of cardiomyocytes exhibited galectin-3 immunoreactivity (Figure 5, G and H). These cardiomyocytes were adjacent to fibrotic areas. Galectin-3 KO hearts served as negative controls and showed no galectin-3 staining after 28 days of TAC, despite the presence of extensive interstitial fibrosis (Figure 5I).

Myocardial Galectin-3 Expression Is Associated with Dilative Remodeling and Systolic Dysfunction, but Not with Hypertrophic Remodeling, after 28 Days of TAC

Next, we examined whether myocardial expression of galectin-3 is a marker of dysfunction and adverse remodeling in pressure-overloaded hearts. After 28 days of TAC, a strong and...
A statistically significant positive correlation was found between the density of galectin-3$^+$ cells and ventricular dimensions (Figure 6, A–C). In addition, a trend toward an inverse correlation was found between the density of galectin-3$^+$ cells and ejection fraction (Figure 6D). In contrast, no association was found between the density of galectin-3$^+$ cells and LV mass ($r = 0.12, P = 0.73$).

Galectin-3 Expression in Cardiomyocytes, but Not in Macrophages, Is Associated with Dilative Remodeling and Systolic Dysfunction

We then examined the association between cell-specific galectin-3 localization and cardiac remodeling after pressure overload. After 28 days of TAC, a strong correlation was found between the density of galectin-3$^+$ cardiomyocytes and ventricular dimensions (Figure 7, A–C). We also noted a trend toward an inverse correlation between the density of galectin-3$^+$ cardiomyocytes and ejection fraction (Figure 7D). Trends were found for weaker correlations between the density of galectin-3$^+$ myofibroblasts and ventricular dimensions (Figure 7, E–G) and a trend for an inverse correlation between the number of galectin-3$^+$-expressing myofibroblasts and ejection fraction (Figure 7H). In contrast, no association was found between the density of galectin-3$^+$ macrophages and the end points that reflect cardiac remodeling, dysfunction, and hypertrophy (galectin-3$^+$ macrophages and LV end-diastolic diameter: $r = 0.10, P = 0.78$; galectin-3$^+$ macrophages and LVEDV: $r = 0.06, P = 0.86$; galectin-3$^+$ macrophages and LV end-systolic volume: $r = -0.06, P = 0.88$; galectin-3$^+$ macrophages and ejection fraction: $r = 0.25, P = 0.53$; galectin-3$^+$ macrophages and LV mass: $r = -0.35, P = 0.32$).

Galectin-3 Loss Does Not Affect Survival after Pressure Overload

To examine whether galectin-3 plays a critical role in remodeling of the pressure-overloaded heart, we compared ventricular dimensions and cardiac function between WT

---

**Figure 6** Ventricular density of gal3$^+$ cells is associated with cardiac remodeling after 28 days of TAC. A–C: Correlation studies reveal statistically significant associations between the density of gal3$^+$ cells and LVEDD (A), LVEDV (B), and LVESV (C). D: A trend was found toward an inverse correlation between the density of gal3$^+$ cells and ejection fraction that does not reach statistical significance. $n = 10$. Gal3, galectin-3; LVEDD, left ventricular end-diastolic diameter; LVEDV, left ventricular end-diastolic volume; LVESD, left ventricular end-systolic diameter; LVESV, left ventricular end-systolic volume; TAC, transverse aortic constriction.

**Figure 7** Ventricular density of gal3$^+$ CMs is associated with adverse remodeling after 28 days of TAC. A–D: A statistically significant correlation was found between the density of gal3$^+$ CMs and left ventricular volumes (B, LVEDV; C, LVESV). Moreover, a trend was found toward a positive correlation between the density of gal3$^+$ CMs and LVEDD (A) and a trend was found toward a negative correlation between the density of gal3$^+$ CMs and ejection fraction (D). E–H: Associations between the density of gal3$^+$ MFs and remodeling-associated variables are weaker and do not reach statistical significance. No significant associations were found between the density of gal3$^+$ macrophages and cardiac remodeling. $n = 10$. ---
and galectin-3 KO mice undergoing TAC protocols. WT and galectin-3 mice had comparable left-to-right carotid flow ratios after TAC (WT, 0.14 ± 0.01; KO, 0.15 ± 0.01) suggesting comparable pressure load between groups. Survival curves were comparable between WT and galectin-3 KO mice (Figure 8A).

Galectin-3 Loss Accelerates Hypertrophy and Delays Chamber Dilation, but Does Not Significantly Affect Function and Remodeling of the Pressure-Overloaded Heart

Heart weight-to-body weight ratio was significantly higher in galectin-3 KO mice after 7 days of TAC (Figure 8, B and C). At the 28-day time point the difference in LV mass between WT and KO mice was no longer significant (Figure 8, B and C). Lung weight/body weight ratio was comparable between groups (Figure 8, D and E). Echocardiographic analysis showed that WT and galectin-3 KO mice had delayed chamber dilation after pressure overload, evidenced by a markedly lower change in LVEDV after 28 days of TAC (Figure 8, D and E). However, changes in LV end-systolic volume and in ejection fraction were comparable between groups (Figure 8, F and G). Galectin-3 KO mice had an accentuated increase in LV mass after 7 days of TAC; however, at the 28-day and 56-day time points, no differences were found between the groups (Figure 8H). Sex-specific analysis showed that galectin-3 loss delayed chamber dilation in female mice but not in male mice undergoing pressure overload protocols (Figure 9).
Galectin-3 Loss Does Not Significantly Affect Diastolic Dysfunction, Collagen Content, and Cardiomyocyte Hypertrophy

We used mitral inflow Doppler echocardiography and tissue Doppler imaging to examine whether galectin-3 loss affects diastolic function in pressure-overloaded hearts. Both WT and galectin-3 KO mice developed tachycardia (Figure 10A) and had increased peak E and A velocities (Figure 10, B and C), associated with a late reduction in the E/A ratio (Figure 10D). Tissue Doppler imaging showed that both WT and galectin-3 KO mice had increased E/E₀ ratio and reduced E₀/A₀ ratio (Figure 10, E and F). These findings are consistent with diastolic dysfunction. No significant differences were found in variables that reflect diastolic function between WT and galectin-3 KO mice.

To examine the effects of galectin-3 on cardiac fibrosis after pressure overload, we performed Sirius red staining in WT and galectin-3 KO hearts after 28 days of TAC (Figure 10G). Quantitative analysis of collagen content found no significant differences in collagen content between WT and galectin-3 null hearts (Figure 10, H–J). Moreover, we used WGA staining to assess the effects of galectin-3 on cardiomyocyte size (Figure 10K) after pressure overload. After 28 days of TAC, cardiomyocyte cross-sectional area was comparable between WT and KO mice (Figure 10, L–N). Sex-specific analysis showed no significant effects of galectin-3 loss on male or female mice (Figure 10, I, J, M and N).

Discussion

Our study reports several novel observations. First, we found that, despite its potential significance as a biomarker in patients with heart failure, galectin-3 plays a noncritical role in the pathogenesis of cardiac remodeling after pressure overload. Global loss of galectin-3 accelerated cardiac hypertrophy and delayed dilative remodeling but did not affect survival, systolic and diastolic dysfunction, fibrosis, and late geometric and functional remodeling of the pressure-overloaded heart. Second, we demonstrate for the first time that galectin-3 is not exclusively localized in macrophages that infiltrate the pressure-overloaded myocardium. Atrial and ventricular cardiomyocytes and activated myofibroblasts exhibit galectin-3 immunoreactivity in the pressure-overloaded mouse heart. Cardiomyocyte-specific galectin-3 localization is associated with adverse remodeling and dysfunction after pressure overload.

In the Pressure-Overloaded Myocardium, Galectin-3 Is Localized in Activated Macrophages, Cardiomyocytes, and Myofibroblasts

Galectin-3 has been identified as a galactose-specific lectin that is abundantly produced by thioglycollate-activated macrophages. In mouse models of tissue injury, galectin-3 immunohistochemistry has been extensively used for identification of activated macrophages. However,
Galectin-3 expression is not limited to cells of the macrophage lineage. Although in many normal mouse tissues (such as the spleen, liver, and lung), galectin-3 immunoreactivity is exclusively localized in macrophages, epithelial cells in the kidney and the intestine also express large amounts of galectin-3 (Figure 1).

Our findings suggest that in the myocardium, galectin-3 localization is not limited to macrophages. In normal adult mouse hearts, atrial but not ventricular cardiomyocytes exhibited constitutive galectin-3 immunoreactivity (Figure 2). We observed marked up-regulation of galectin-3 in the pressure-overloaded heart, confirming similar findings in other models of hypertrophic cardiac remodeling.21 Transgenic rats overexpressing the mouse renin gene (Ren-2) exhibit severe hypertension and develop marked cardiac hypertrophy followed by decompensation and overt heart failure.41 Cardiac remodeling in Ren-2 rats is associated with marked up-regulation of galectin-3 expression that is predominantly localized in infiltrating macrophages.21 As expected, in our model of TAC-induced cardiac pressure overload, myocardial remodeling was also associated with infiltration of numerous galectin-3+ macrophages (Figure 3). Because cytokine stimulation has been previously implicated in galectin-3 up-regulation in macrophages,42,43 we examined

Figure 10  Galectin-3 loss does not affect diastolic dysfunction, fibrosis, and cardiomyocyte hypertrophy in the pressure-overloaded myocardium. A–F: Doppler echocardiography and tissue Doppler imaging shows that galectin-3 absence does not affect diastolic function. TAC increases (A) and peak E (B) and A (C) velocities in both WT and galectin-3 KO mice. The E/A ratio is significantly reduced in WT mice after 56 days of TAC (D). The E/E’ ratio, a sensitive indicator of diastolic dysfunction, increases after TAC in both WT and galectin-3 KO mice (E), whereas the E’/A’ ratio is reduced (F). Galectin-3 loss has no effects on indicators of diastolic dysfunction. G–J: Sirius red staining was used to label collagen fibers in WT and galectin-3 KO hearts after 28 days of TAC. No statistically significant difference was noted between WT and KO mice (H) in both male and female groups. K–N: Cardiomyocyte size was assessed in sections stained for WGA lectin. Cardiomyocyte size was comparable in WT and galectin-3 KO mice after 28 days of TAC (L), in both male and female mice. Data are expressed as means ± SEM, n = 10 to 16 per group (A–F); n = 9 to 10 per group (K–N). *P < 0.05, **P < 0.01 versus corresponding pre. Scale bar = 60 μm. Bpm, beats per minute; HR, heart rate; KO, knockout; TAC, transverse aortic constriction; WT, wild-type.
whether IL-1β and TGF-β1, cytokines critically involved in cardiac remodeling, regulate macrophage galectin-3 synthesis. Unstimulated splenic macrophages expressed high levels of galectin-3; however, both IL-1β and activation of the TGF-β1/Smad pathway suppressed galectin-3 synthesis (Figure 4). Smad3 absence abrogated the down-modulatory effects of IL-1β, suggesting that the actions of the cytokine may involve indirect stimulation of a Smad-dependent TGF-β cascade. Macrophages are highly heterogeneous and exhibit distinct properties, depending on the tissue of origin; thus, whether responses of splenic macrophages to cytokine stimulation are relevant in cardiac remodeling is unclear.

After 7 days of pressure overload, a subset of myofibroblasts also expressed galectin-3. Expression of galectin-3 by fibroblasts has been previously reported. Our experiments showed that approximately 10% of unstimulated cardiac fibroblasts expressed galectin-3 when cultured in collagen pads (Figure 4). IL-1β and TGF-β stimulation did not increase galectin-3 expression in cardiac fibroblasts (Figure 4), suggesting that the increased number of galectin-3 myofibroblasts in the remodeling myocardium may not directly result from cytokine stimulation but may reflect the increased infiltration of the pressure-overloaded myocardium with abundant activated fibroblasts.

Surprisingly, after 7 to 28 days of pressure overload, intense galectin-3 immunoreactivity was localized in a subset of ventricular cardiomyocytes. Galectin-3 expression by cardiomyocytes has not been previously reported in vivo or in vitro. We demonstrated the specificity of Mac2 immunohistochemistry in detection of galectin-3 by showing absence of staining in pressure-overloaded galectin-3 KO hearts (Figure 5). Moreover, the clear cytoplasmic localization of galectin-3 in a subset of ventricular cardiomyocytes in fibrotic myocardial areas (Figure 5) suggests that immunoreactivity does not result from binding of the protein to the cell surface. Whether galectin-3 localization in cardiomyocytes of the pressure-overloaded heart indicates active synthesis or reflects the transfer of protein produced by other cell types (such as macrophages or myofibroblasts) remains unclear.

Galectin-3 in Cardiomyocytes Is Associated with Dysfunction and Adverse Remodeling

The significance of galectin-3 expression in regulation of the biological properties of cardiomyocytes remains unclear. Our findings indicated that a high density of galectin-3+ cardiomyocytes was associated with adverse remodeling and dysfunction in pressure-overloaded hearts. The absence of major effects of galectin-3 loss in cardiac remodeling suggests that cardiomyocyte-specific galectin-3 is unlikely to play a crucial role in cardiomyocyte responses to pressure overload. Thus, expression of galectin-3 in cardiomyocytes may represent an epiphenomenon that reflects another injurious cellular process. Protective effects of galectin-3 in apoptotic responses have been extensively reported; whether expression of galectin-3 by selected cardiomyocytes serves a protective role against apoptosis is unclear. However, the absence of significant effects of galectin-3 loss on cardiac function does not support a crucial effect of galectin-3 in protecting cardiomyocytes in the pressure-overloaded heart.

Does Galectin-3 Play a Role in Cardiac Remodeling?

In vitro and in vivo studies have suggested an important role for galectin-3 in regulation of inflammatory and fibrotic responses. Studies on the role of galectin-3 in inflammation have produced contradictory results, likely reflecting the context-dependent actions of intracellular and matrix-bound galectin-3 in a variety of cell types. In a model of thioglycollate-induced peritonitis, galectin-3 KO animals exhibited attenuated peritoneal inflammation, and loss of galectin-3 increased apoptosis of proinflammatory macrophages and decreased NF-κB signaling. In contrast, in a model of endotoxemia, galectin-3 loss was associated with an accentuated inflammatory response, suggesting that it may serve as a negative regulator of endotoxin-induced proinflammatory activation.

Galectin-3 expression is consistently induced in models of fibrosis; its up-regulation is associated with activation of a profibrotic program. In experimental hepatic fibrosis, galectin-3 loss inhibited myofibroblast activation by attenuating TGF-β-mediated responses. Profibrotic actions of galectin-3 were also reported in models of renal and pulmonary injury. In models of fibrotic cardiomyopathy induced by pressure overload, Yu et al suggested that galectin-3 plays an important role in the pathogenesis of fibrosis and dysfunction. Moreover, in a model of aldosterone-induced cardiac fibrosis, galectin-3 was critically involved in fibroblast activation. Our findings, based on a higher number of mice, do not support these published observations. With the use of the same loss-of-function model, we found no significant effects of galectin-3 loss on cardiac dysfunction and fibrosis in the pressure-overloaded heart. The disparate findings may reflect sex-specific effects: in the study by Yu et al., and in the investigations on the model of aldosterone-induced cardiomyopathy only male animals were studied. Sex-specific analysis of the echocardiographic data showed that galectin-3 loss delayed dilation of the pressure-overloaded heart in female mice (Figure 9) but did not suggest protective actions of galectin-3 in male animals. Moreover, differences in the severity of the pressure load and exclusive focus on a single time point may account for the distinct observations. In our investigation, assessment of the carotid flow ratio ensures comparable pressure gradients between WT and KO mice. Moreover, we performed systematic analysis of cardiac remodeling and function after 7, 28, and 56 days of TAC to investigate the consequences.
of galectin-3 loss in the transition from hypertrophic to dilative remodeling.

Our observations suggested that galectin-3 loss may delay the hypertrophic response after pressure overload. The findings may suggest direct activation of a hypertrophic program in cardiomyocytes by galectin-3 or may reflect galectin-3—mediated modulation of macrophages toward a phenotype that promotes hypertrophy. Note that the absence of significant differences in function and geometry between WT and galectin-3 KO mice may reflect competing actions of galectin-3 on various cell types involved in cardiac remodeling.

**Conclusions**

Despite its role as a biomarker that mirrors the progression and severity of heart failure, galectin-3 does not play a crucial role in the pathogenesis of the fibrotic cardiomyopathy associated with pressure overload. Useful and reliable biomarkers of cardiac remodeling do not necessarily serve a key biological function, but they may be released after stress, reflecting another injurious process. Galectin-3 localization in atrial and ventricular cardiomyocytes and expression by infiltrating myofibroblasts may be an indicator of myocardial injury and fibrosis, thus explaining the association between galectin-3 levels and adverse prognosis.
