Toll-like receptors (TLRs) are one of the main contributors that induce inflammation under tissue injury and infection. Because excessive inflammation can aggravate disease states, it is important to control inflammation at a moderate level. Herein, we show that hyaluronan (HA) oligomer, HA tetrasaccharide (HA₄), could suppress the expression of proinflammatory cytokine IL-1β when stimulated with both TLR2- and TLR4-specific agonists in primary hippocampal neurons. To understand the effect of HA₄ against ischemic insult, we performed hypoxic-ischemic (H/I) brain injury against neonatal mice. HA₄ treatment significantly prevented hippocampal pyramidal cell death even 7 days after H/I injury, compared with the control mice. Although TLR2 and TLR4 are known as receptors for HA and also act as a receptor for inducing inflammation, only TLR2-deficient mice showed tolerance against H/I injury. Moreover, HA₄ administration suppressed gliosis by inhibiting the activation of NF-κB, the downstream target of TLR2, which led to the suppression of IL-1β expression. Taken together, our data suggest that the neuroprotective effect of HA₄ relies on antagonizing the TLR2/NF-κB pathway to reduce inflammation through suppressing the expression of proinflammatory cytokines after neonatal H/I brain injury. (Am J Pathol 2016, 186: 2143–2151; http://dx.doi.org/10.1016/j.ajpath.2016.03.016)
patterns (DAMPs), even in the absence of infection. Accumulation of DAMPs initiates positive feedback loops of inflammation that increases tissue damage after impairment. Therefore, regulating the TLR signaling pathway is important for managing pathological conditions.

Although hyaluronan (HA) is known as one of the DAMPs that stimulates TLR2 and TLR4, interestingly, the activity of HA depends on size. In general, high-molecular-weight-HA (HMW-HA; $6 \times 10^5$ to $1 \times 10^6$ Da) is anti-inflammatory, anti-inflammatory, and immunosuppressive, whereas low-molecular-weight-HA (LMW-HA; $<5 \times 10^4$ Da) is inflammatory, immunostimulatory, and angiogenic. However, the definition of LMW-HA is ambiguous and little is known about small HA oligomers.

Herein, we revealed the effect of a small HA oligomer, HA tetrasaccharide (HA4; 820.24 Da) against neonatal H/I brain injury. Several recent articles reported that HA4 treatment has improvement in a symptom after spinal cord injury or experimental autoimmune encephalomyelitis. However, little is known about the underlying molecular mechanisms. To further elucidate the effects of HA4 after neonatal H/I brain injury, we focused on the relationship between TLRs and the induction of inflammation.

Materials and Methods

Animals

The procedures involving animal care, surgery, and sample preparation were approved by the Animal Experimental Committee of Juntendo University (Tokyo, Japan) and performed in accordance with the Guide for the Care and Use of Laboratory Animals. Neonatal C57BL/6J mice were obtained from Japan SLC (Shizuoka, Japan), and the C57BL/6 background TLR2 and TLR4 knockout (KO) mice were purchased from Oriental BioService (Kyoto, Japan). Mice were subsequently housed under specific pathogen-free conditions with a 12-hour light-dark cycle at Juntendo University.

Hypoxic-Ischemic Injury

Neonatal H/I brain injury was induced in mice on post-natal day 7 (P7), essentially according to the Rice-Vannucci model with minor modifications. After the mice were deeply anesthetized with isoflurane (2%), the left common carotid artery was dissected and ligated with silk sutures (6/0), followed by a recovery for 1 hour at 37°C. They were then placed in chambers maintained at 37°C with a flow purged with nitrogen gas to control oxygen concentration to 8% for 25 minutes. After hypoxic exposure, the pups were returned to their dams and were allowed to recover for 1, 3, 6, 12, and 24 hours, and 7 days. At each stage, the brains were processed for molecular, biochemical, and morphological analyses. This procedure resulted in brain injury in the ipsilateral hemisphere, consisting of cerebral infarction mainly in the hippocampus. Pups with severe damage in the cortex were eliminated from the experiment. Control littermates were neither operated on nor subjected to hypoxia.

Preparation of Hyaluronan Tetrasaccharide

Preparation of HA4 was as follows. Hyaluronan (Shiseido, Tokyo, Japan) was digested in 0.3 mol/L methanesulfonic acid at 80°C for several hours (18 to 20 hours). The digest was diluted in water and then adjusted to a pH between 5 and 7 with sodium hydroxide before being loaded onto a column containing Dowex 1 x 4 anion exchange resin (Wako Chemical, Osaka, Japan; 200 to 400 mesh). The 1 x 4 column was washed with an aqueous 40 mmol/L sodium chloride solution, and HA4 was eluted with a linear gradient consisting of 40 to 100 mmol/L sodium chloride. The Dowex 1 x 4 purified HA4 was adjusted to between pH 4 and pH 5 with HCl, diluted with water, and loaded onto a column containing BioRad High Q (anion exchange) resin (Bio-Rad Laboratories, Hercules, CA). The High Q column was washed with water, and HA4 was eluted with 0.5 mol/L sodium chloride. The pH of the eluted HA4 solution was adjusted to pH approximately 5 with HCl, concentrated by rotary evaporation, and then desalted by passing it through a BioGel P2 size exclusion column (Bio-Rad Laboratories) using water as the eluant. The desalted HA4 was purified with a Dowex 50Wx4 column (Wako Chemical) in the acid form. This purified HA4 was passed through ultrafilter membranes with a molecular weight cutoff of 10,000 Da (Merck Millipore, Darmstadt, Germany), concentrated, and then dried to a powder in a rotary evaporator. The purity of HA4 was determined by high-performance liquid chromatography.

Hyaluronan Administration

HA4 was administered i.p. to P6 mouse pups 12 hours before, and just before, H/I injury at P7 with a concentration of 10 mg/kg body weight. Saline administration was performed against littermates or age-matched mice as a control.

Sample Preparation for Histochemical and Morphological Analyses

After H/I injury, mice were deeply anesthetized and fixed by cardiac perfusion with 4% paraformaldehyde buffered with 0.1 mol/L phosphate buffer (pH 7.2) containing 4% sucrose. Brain tissues were quickly removed from the mice and further immersed in the same fixative overnight at 4°C. Samples processed for paraffin embedding were cut into sections (4-μm thick) with a semimotorized rotary microtome (RM2245; Leica, Wetzlar, Germany) and placed on silane-coated glass slides. For routine histological studies, paraffin sections were stained with hematoxylin and eosin.

Immunoblot Analysis

Each tissue was independently homogenized in RIPA buffer [50 mmol/L Tris-HCl (pH 7.6) with 150 mmol/L...
NaCl, 1% NP-40, 0.5% sodium deoxycholate, and 0.1% SDS) containing a protease inhibitor-cocktail (Nacalai, Shiga, Japan) and a phosphatase inhibitor-cocktail (Nacalai). After centrifugation at 20,000 \times g for 10 minutes at 4°C, the protein concentrations in the supernatants were determined using the BCA protein assay system (Pierce, Rockford, IL), and were used for immunoblotting. The lysates were eluted by boiling in loading buffer, separated by SDS-PAGE, and transferred to an Immobilon P-membrane (Millipore). The blots were probed with anti-\(\text{NF-kB}\) p65 antibodies (1:1000; Cell Signaling Technology, Danvers, MA) and anti--phospho-\(\text{NF-kB}\) p65 (Ser536) antibodies (1:500; Cell Signaling Technology).

Immunohistochemical Analysis

Deparaffinized sections were incubated overnight at 4°C with anti-NeuN antibodies (1:200; Merck Millipore), anti-Iba1 antibodies (1:200; Wako), anti-Mac2 antibodies (1:200; Cedarlane, Burlington, NC), and anti--glial fibrillary acidic protein antibodies (1:200; Sigma, St. Louis, MO). Sections were further reacted with peroxidase-conjugated secondary antibodies at room temperature for 2 hours and washed three more times. To visualize the sections, they were reacted with peroxidase, using 0.0125% \(\text{H}_{2}\text{O}_{2}\) in 0.05 mol/L Tris-HCl buffer (pH 7.6) for 5 minutes. For immunofluorescence staining antimouse, anti-rabbit IgG Alexa Fluor 488 antibodies (Thermo Fisher Scientific, Rockford, IL), and anti-rat Cy3 antibodies (Jackson ImmunoResearch Laboratories, West Grove, PA) were used as secondary antibodies. Immunostained sections were observed using a BX50 (Olympus, Tokyo, Japan) and confocal laser scanning microscope FV1000 (Olympus).

qPCR and RT-PCR

For real-time quantitative PCR (qPCR) and RT-PCR analyses, total RNA was prepared using RNeasy (Qiagen, Hilden, Germany) and cDNA was synthesized using a PrimeScript master mix (Takara, Kyoto, Japan) and a phosphatase inhibitor-cocktail (Nacalai). After centrifugation at 20,000 \times g for 10 minutes at 4°C, the protein concentrations in the supernatants were determined using the BCA protein assay system (Pierce, Rockford, IL), and were used for immunoblotting. The lysates were eluted by boiling in loading buffer, separated by SDS-PAGE, and transferred to an Immobilon P-membrane (Millipore). The blots were probed with anti--\(\text{NF-kB}\) p65 antibodies (1:1000; Cell Signaling Technology, Danvers, MA) and anti--phospho-\(\text{NF-kB}\) p65 (Ser536) antibodies (1:500; Cell Signaling Technology).

Primary Cultures of Hippocampal Neurons

Primary hippocampal neurons were prepared for culturing, as previously described. Briefly, the hippocampi were dissected and dissociated from 18-day-old fetal mice. Dissociated hippocampal neurons were plated on poly-l-ornithine (Sigma) coated 6-well plates with 2% B27 (Invitrogen, San Diego, CA) and 2 mmol/L \(\text{l-glutamine}\) (Nacalai) in Neurobasal medium (Invitrogen). Two days later, 10 mmol/L cytosine arabinoside (Nacalai) was added to inhibit nonneuronal growth. After 14 days, hippocampal neurons were stimulated with 1 \(\mu\)g/mL Pam3CSK4 (Invivogen) and 1 \(\mu\)g/mL LPS-SM Ultrapure (Invivogen) in the presence (50 ng/mL, 5 \(\mu\)g/mL) or absence of HA4 for 6 hours on day 14.

TUNEL Staining

Terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL) staining was applied to deparaffinized sections as previously described. Briefly, sections were incubated with 100 U/mL TdT (Promega, Madison, WI) and 10 nmol/L biotinylated 16-2'-dUTP (Roche Diagnostics, Basel, Switzerland) in TdT buffer (100 mmol/L sodium cacodylate, pH 7.0, 1 mmol/L cobalt chloride, 50 mg/mL gelatin) in a humid atmosphere at 37°C for 1 hour, followed by further incubation with peroxidase-conjugated streptavidin (Vector Laboratories, Burlingame, CA) for 1 hour at room temperature. Staining for peroxidase was performed as stated above.

Cell Counting

The number of TUNEL-positive cells was counted in the whole pyramidal regions of the hippocampus, located in the same portion (bregma: -1.82 mm of adult C57BL/J mice), according to the previous report.

Neuropathological Evaluation

H/I injury and neuroprotection were evaluated by the number of TUNEL-positive (dead) cells in the pyramidal layers of the hippocampus 24 hours after H/I injury using brain sections corresponding to the same portion of the hippocampus as mentioned above. The damaged area in the hippocampal pyramidal layers was also examined 7 days after H/I injury, in which time clear-cut shrinkage occurred in the ipsilateral hippocampus of the control mice, resulting in a loss of ipsilateral hippocampal neurons. To quantitate these damaged areas after neonatal H/I, the areas of lesioned and unlesioned hippocampi were measured and compared within the same section corresponding to the same portions mentioned above, using ImageJ software version 1.38 (NIH, Bethesda, MD). The area loss of the lesioned ipsilateral hippocampus was calculated as a percentage of the intact contralateral hippocampus, and was determined for each animal.
Statistical Analysis

All quantified data were expressed as the means ± SEM. Differences between two mean values were evaluated using an unpaired Student’s t-test and two-way analysis of variance post-hoc tests that were considered statistically significant when the P value was <0.05.

Results

HA4 Antagonizes Both TLR2 and TLR4 Signaling Pathway in Primary Hippocampal Neurons

The hippocampus is the brain region that is most vulnerable to cerebral ischemic insult,18,19 and Toll-like receptors (TLRs) are known to be involved in neuronal cell death after ischemia.22–25 To determine the effect of a small HA oligomer, HA tetrasaccharide (HA4; 820.24 Da), we focused on the TLR signaling pathway for three reasons: i) TLR2 and TLR4 are known as the receptors for HA10,11; ii) stimulation of TLRs would activate NF-κB and induce proinflammatory cytokines; and iii) primary cortical neurons generated from TLR2-KO and TLR4-KO mice are resistant to glucose deprivation.22 Therefore, we first explored whether HA4 could participate in the TLR/NF-κB signaling pathway in primary hippocampal neurons. To confirm the expressions of TLR2 and TLR4 in primary hippocampal neurons, we performed reverse transcriptase-PCR. Primary hippocampal neurons cultured for 14 days in vitro expressed both TLR2 and TLR4 as well as the microglial cell line BV2 (Figure 1A). Thus, we stimulated TLR2 and TLR4 with specific agonists, Pam3CSK4 and LPS, respectively, and observed the expression of the proinflammatory cytokine IL-1β by qPCR in the presence and absence of HA4. The increased expression of IL-1β by Pam3CSK4 stimulation (2.7-fold) and LPS stimulation (2.8-fold) was suppressed in a dose-dependent manner by HA4 administration (50 ng/mL, 5 μg/mL of HA4, respectively), whereas no change was observed when HA4 was administered alone (Figure 1B). These data suggest that HA4 can play an antagonistic role against TLR2 and TLR4 in the hippocampal neuron in vitro.

HA4 Administration Protects Hippocampal Pyramidal Neurons from Neonatal H/I Injury

To elucidate the effect that HA4 administration exerts against cerebral ischemic insult in vivo, we next examined the damage in the pyramidal regions of the hippocampus in neonatal mouse brains after H/I injury. HA4 (10 mg/kg body weight) was administered i.p., 12 hours, and immediately before H/I injury, and physiological saline was injected as a control. The degree of damage in the hippocampal pyramidal cells, quantified as the number of TUNEL-positive nuclei, was extremely reduced in mice treated with HA4, compared with those treated with saline 24 hours after H/I injury (Figure 2, A–D). The number of TUNEL-positive nuclei within the pyramidal layer of mouse brains (Figure 2, B and D) that were administered with HA4 was significantly decreased (179 ± 19) to fewer than half the number of those treated with saline (377 ± 51) (Figure 2E). We further evaluated the number of TUNEL-positive nuclei, in the CA1 and CA3 region of the hippocampal pyramidal cell layer. The number of TUNEL-positive nuclei within CA1 region (Figure 2F) significantly decreased by HA4 administration (44 ± 10) compared with saline (214 ± 30). However, although slight reduction of the number of TUNEL-positive nuclei was also observed, no significance was detected between HA4 (17 ± 6) and saline (61 ± 24) administration in the CA3 region (Figure 2F). These data suggest that HA4 administration can protect hippocampal pyramidal cells after neonatal H/I brain injury in a region-specific manner.

Pathological Alterations Are Not Detected in the Hippocampal Pyramidal Neurons of a HA4-Administered Neonatal Hippocampus 7 Days after H/I Injury

Delayed neuronal death reportedly occurs in the pyramidal layers of the hippocampus within 7 days after transient brain ischemia, and damaged areas are replaced by glial cells.19
To exclude the possibility that the administration of HA4 simply delayed the onset of pyramidal cell death, we further analyzed the degree of damage in the neurons of the hippocampal pyramidal layers in HA4-administered and control littermate mice 7 days after H/I injury. Loss of NeuN-positive neurons with their neurites that was eliminated by microglial cells contributed to the areal reduction of pyramidal layers of the control mouse hippocampus (Figure 3, C and D). The total area of the ipsilateral hippocampus was significantly diminished, compared with the contralateral hippocampus (Figure 3, A and B). Meanwhile, in the HA4-administered mice, the remaining pyramidal neurons were largely TUNEL-negative (data not shown), and staining for hematoxylin and eosin, and NeuN showed those neurons to be intact (Figure 3, A–F). The ipsilateral hippocampal area in the HA4-administered mice was only slightly diminished to 96% ± 9% compared with the contralateral hippocampus (Figure 3, B and G). However, in the physiological saline-injected littermate controls, the ipsilateral hippocampal area was reduced to nearly half the contralateral hippocampal area 7 days after H/I injury (53% ± 7%) (Figure 3, A and G). These data indicate that the prevention of hippocampal pyramidal cell death by HA4 administration is sustained at least until 7 days after H/I injury.

The Neuroprotective Effect of HA4 Largely Relies on the Inhibition of TLR2, but Not TLR4 in Neonatal H/I Injury

HA4 antagonized both TLR2 and TLR4 in primary hippocampal neurons in vitro (Figure 1) and protected hippocampal pyramidal cells after H/I injury in vivo (Figures 2 and 3). However, the major target of the neuroprotective role of HA4 after neonatal H/I injury remained unclear. To confirm the relationship between TLR2, TLR4, and HA4 in vivo, we used TLR2-KO and TLR4-KO mice and applied them to H/I injury. When saline was administered, the degree of damage in the hippocampal pyramidal cells was extremely reduced in TLR2-KO mice (Figure 4C), compared

- **Figure 2** HA4 administration protects hippocampal pyramidal cells from neonatal H/I injury. Representative demonstration of the ipsilateral hippocampi of mice administered saline (A and B) and HA4 (C and D), respectively, stained with hematoxylin and eosin (H&E; A and C) and for terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL; B and D) 24 hours after H/I injury. E: Quantitative analysis of the number of TUNEL-positive cells in the pyramidal layer of an identical portion (bregma: -1.82 mm of adult C57BL/J mice) of the hippocampus, administered saline and HA4, 24 hours after H/I injury. F: Quantitative analysis of the number of TUNEL-positive cells in the CA1 and CA3 region of an identical portion (bregma: -1.82 mm of adult C57BL/J mice) of the hippocampus, administered saline and HA4, 24 hours after H/I injury. Data are expressed as means ± SEM (E and F). n = 13 and 14 mice per group (E); n = 8 and 6 mice per group (F). **P < 0.01, ***P < 0.001. Scale bar = 200 μm (A–D).

- **Figure 3** Prevention of neuronal loss in the hippocampus by HA4 administration is further sustained up to 7 days after H/I injury. Representative demonstration of the hippocampi of mice administered saline (A, C, and E) or HA4 (B, D, and F) stained with hematoxylin and eosin (H&E; A and B) and anti-NeuN antibodies (C–F) 7 days after H/I injury. G: Evaluation of the area of ipsilateral (Ipsi) against contralateral (Contra) hippocampi of HA4-treated and littermate control mouse brains of an identical portion (bregma: -1.82 mm of adult C57BL/J mice) of the hippocampus 7 days after H/I injury. Data are expressed as means ± SEM (G). n = 9 and 7 mice per group (G). **P < 0.01. Scale bars: 400 μm (A–D); 200 μm (E and F).
Together, these data indicate that the major target of HA4 after neonatal H/I brain injury was TLR2 but not TLR4.

HA4 Administration Inhibits the Expression of Proinflammatory Cytokine IL-1β through Inactivating NF-κB after H/I Injury

H/I injury induces an inflammatory reaction in the neonatal brain, and the early proinflammatory phase is thought to deteriorate pathological states. Inhibition of proinflammatory cytokines, such as IL-1β and IL-18, and the activator of IL-1 and IL-18, caspase-1, reduces H/I brain injury to a moderate degree. Therefore, we evaluated the expression level of IL-1β in the ipsilateral hippocampus with or without HA4 administration and compared with TLR2-KO mice by qPCR. The expression level of IL-1β increased within an hour and peaked 6 hours after H/I injury in the control mice (Figure 5A). However, HA4 administration, as well as TLR2-KO mice, significantly inhibited IL-1β expression 3 and 6 hours after H/I injury (Figure 5A). To further confirm the molecular mechanism regulating the expression of IL-1β, we next verified the activity of the NF-κB family. The Ser536 residue of p65/RelA, a member of the NF-κB/Rel family, is phosphorylated when NF-κB is activated and translocates to the nucleus to regulate gene expression including IL-1β. Western blot analyses revealed that the activation of NF-κB in the ipsilateral hippocampi, represented as an expression ratio of phospho-p65/RelA (Ser536) per pan-p65/RelA, increased 5.2-fold within an hour in control mice when compared with sham-operated mice, whereas the activation was significantly suppressed to 1.4-fold by HA4 administration and 0.98-fold in TLR2-KO mice (Figure 5, B and C). These data indicate that HA4 administration can inhibit the expression of proinflammatory cytokine IL-1β in vivo, in a closely related manner to TLR2-KO mice, by inactivating NF-κB in the early stages after H/I Injury.

HA4 Administration Inhibits Gliosis after H/I Injury

Although the expression of IL-1β mRNA was suppressed by HA4 administration (Figure 5), the activation (cleavage for the secretion form) of IL-1β, which causes inflammation, was undetectable by both Western blot analyses and enzyme-linked immunosorbent assay analyses after H/I brain injury. Therefore, we focused on gliosis as the hallmark of inflammation. Gliosis consists of the activation of astrocytes and microglial cells, stimulated by proinflammatory cytokines, including IL-1β. The activation of microglial cells and astrocytes was investigated by evaluating the expression of Mac2 (for reactive microglial cells), Iba1 (for pan-microglial cells), and glial fibrillary acidic protein (for reactive astrocytes) 24 hours after H/I injury (Figure 6). Interestingly, the Iba1-positive microglial cells slightly increased the number and many coexpressed Mac2 in the control hippocampus (Figure 6A), whereas HA4

Figure 4 TLR2 is the major target for the neuroprotective effect of HA4 after H/I injury in vivo. Representative demonstration of the ipsilateral hippocampus of wild-type (A and B), TLR2-KO (C–F), and TLR4-KO (G–J) mice administered saline (A–D, G, and H) or HA4 (E, F, I, and J), and obtained 24 hours after H/I injury. A, C, E, G, and I: Hematoxylin and eosin (H&E) staining. B, D, F, H, and J: Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) staining. K: Quantification of the number of TUNEL-positive cells in the pyramidal layer of an identical portion (bregma: -1.82 mm of adult C57BL/J mice) of the hippocampus of wild-type, TLR2-KO, and TLR4-KO mice administered saline or HA4 and obtained 24 hours after H/I injury. Data are expressed as means ± SEM (K), n = 6 or 7 mice per group (K). *P < 0.05, **P < 0.01. Scale bar = 200 μm (A–J).
administration diminished the expression of Iba1 to the steady state and Mac2-expressing cells were not observed (Figure 6B). Moreover, the expression of glial fibrillary acidic protein was strongly elevated only in the control hippocampus, suggesting that HA4 administration suppressed the emergence of reactive astrocytes (Figure 6C and D). Taken together, these data indicate that HA4 administration protects neuronal cell death through suppressing inflammation via inhibiting the expression of proinflammatory cytokine IL-1β.

Discussion

Inflammation is induced by both tissue injury and infection for facilitating wound healing and stimulating innate immunity. However, excessive inflammation can also aggravate symptoms. Although lines of evidence from KO animals have revealed that TLRs are one of the main contributors not only to pathogen-induced inflammation, but also to injury-induced inflammation in various organs, the strategies to attenuate inflammation after tissue damage have been limited. Herein, we demonstrated the following five points: i) HA4 exhibited antagonistic action against both TLR2 and TLR4 in vitro; ii) HA4 administration prevented hippocampal pyramidal neuron death for at least 7 days after neonatal H/I brain injury; iii) the main target of this inhibition was TLR2 but not TLR4 in vivo; iv) HA4 administration decreased the expression of proinflammatory cytokine IL-1β by inactivating the NF-κB/Rel family; and v) HA4 administration prevented inflammation.

HA has a high molecular mass (>10^6 Da) under physiological conditions. However, in inflammatory tissues, the activation of hyaluronidase degrades HMW-HA into small

**Figure 6** The emergence of Mac2-expressing microglial cells and reactive astrocytes is suppressed by HA4 administration 24 hours after H/I injury. Representative demonstration of the ipsilateral hippocampi administered saline (A and C) and HA4 (B and D) stained with anti-Iba1 antibodies (green; A and B), anti–glial fibrillary acidic protein (GFAP) antibodies (green; C and D), anti-Mac2 antibodies (red; A–D), and DAPI (blue; A–D). Scale bar = 50 μm (A–D).
fragments, whereas increased free radicals also depolymerize HMW-HA.\textsuperscript{31,32} Such fragmented or depolymerized LMW-HA molecules (1 to 2.5 × 10\textsuperscript{4} Da) are known to be potent stimulators of inflammatory cytokines through TLR2 and TLR4. During acute lung injury, depolymerized LMW-HA (1.35 to 2 × 10\textsuperscript{4} Da) fragments will cause inflammation through both TLR2 and TLR4 \textit{in vivo}.\textsuperscript{33} Conversely, forced expression of HMW-HA (>10\textsuperscript{6} Da) exerts protective effects on lung injury and epithelial cell apoptosis.\textsuperscript{34} Our finding that the small HA oligomer (HA4) administration protected mice from H/I injury (Figures 2 and 3) may explain the diverse biological effects of HA and its fragments.

Our present data suggested that the neuroprotective effect of HA4 results from the antagonistic action against TLR to prevent the expression of proinflammatory cytokine IL-1β that leads to inflammation (Figures 1, 5, and 6). Our hypothesis concerning how HA4 can antagonize the TLR/NF-κB pathway is as follows. Because HA is a straight chain of nonsulfated glycosaminoglycan that is composed of repeating polymeric disaccharides, d-glucuronic acid and N-acetyl glucosamine, it is plausible that HA can be accessible to TLR2 and TLR4 as well as LMW-HA. Ligand-induced receptor dimerization of TLR is a crucial step to launch the cascade that finally results in the activation of several transcription factors, including NF-κB.\textsuperscript{7} We speculate that HA4 binds to TLR2 and TLR4 and fills the pocket to block the binding of stimulants, but that it is too small to couple the receptors to activate the cascade. Therefore, HA4 can suppress the expression of proinflammatory cytokines by inactivating the TLR/NF-κB pathway. Consistent with our hypothesis, several groups have suggested that HA oligomers could attenuate the hyaluronan signaling by displacing multivalent HA polymers and inhibiting the malignant progression in various kinds of cancer.\textsuperscript{31,32}

We have previously reported that HA4 up-regulates the expression of Hsp72 (an inducible form of Hsp70) and heat shock factor-1, and that it can prevent cell death under serum deprivation of neuronally differentiated PC12 cells.\textsuperscript{35} In the current study, we did not observe the expression of Hsp72. However, it is known that overexpression of Hsp70 attenuates brain damage after permanent and transient middle cerebral artery occlusion by reducing inflammation in adult mice.\textsuperscript{36,37} In addition, overexpression of Hsp70 decreases the release of IL-1β when macrophages were stimulated with high mobility group box 1.\textsuperscript{38} Although the regulatory mechanism is yet unclear, we will not exclude the possibility that the recovery observed by HA4 administration is because of an increase in Hsp70 expression.

The number of TUNEL-positive nuclei dramatically decreased by HA4 administration throughout the entire hippocampal pyramidal layer (Figure 2E), and the CA1 region showed comparable results (Figure 2F). However, despite the slight reduction (61 ± 24 to 17 ± 6 by HA4 administration) (Figure 2F), no significant differences were observed in the CA3 region. Because the number of TUNEL-positive nuclei were limited and distinction between samples was extensive, one interpretation could be the insufficiency of samples; however, this could be also rationalized by the difference of the cell death mode between CA1 and CA3 pyramidal cells.\textsuperscript{3}

TLR2 and TLR4 are both known to be involved in neuronal cell death after cerebral ischemia-reperfusion in adults.\textsuperscript{25} In addition, HA4 administration antagonized specific agonists against both TLR2 and TLR4 in primary hippocampal neurons (Figure 1). However, the neonatal H/I injury model revealed that the major target of the neuroprotective role of HA4 was TLR2 but not TLR4 (Figure 4). This discrepancy could be because of the expression patterns of TLR2 and TLR4 \textit{in vitro} and \textit{in vivo}. Although we confirmed that TLR2 and TLR4 were both expressed in primary hippocampal neurons and the neonatal hippocampus by reverse transcriptase-PCR (Figure 1), we could not quantify the precise expression amounts of either TLR2 or TLR4, nor could we determine which cells were responsible for the promotion of inflammation. However, because TLR4-KO mice showed no significant recovery against the control mice after H/I injury, HA4 administration and TLR2-KO could protect hippocampal pyramidal cell death to the equivalent level (Figure 4), it is possible to predict that the expression of TLR4 has little effect on hippocampal neuronal cell death after neonatal H/I injury.

A recent report has shown that the peroxiredoxin family proteins released extracellularly after brain ischemia-reperfusion injury in adult mice stimulate TLR2 and TLR4 as a DAMP.\textsuperscript{25} Interestingly, the blocking antibodies attenuated ischemic brain damage and suppressed inflammatory cytokine expression when systemically administered even 12 hours after ischemia.\textsuperscript{25} These data suggest that targeting TLRs could expand the therapeutic window after stroke. A large body of evidence suggests that TLR2 and/or TLR4 play a pivotal role in ischemia-reperfusion injuries in various organs (ie, hepatic, renal, cerebral, intestinal, and myocardial).\textsuperscript{30} Thus, HA4 could be an attractive candidate for clinical applications in ischemic insult. Moreover, although the recurrence rate after perinatal stroke is lower than in older children and adults,\textsuperscript{2} prophylactic efficacy of HA4 could be expected against stroke in newborn infants.
