Type 2 diabetes mellitus (T2DM) is a major risk factor for heart disease. Mortality rates after myocardial infarction (MI) are significantly increased in T2DM patients because of dysfunctional left ventricle (LV). However, molecular pathways underlying accelerated heart failure (HF) after MI in T2DM remain unclear. We investigated the underlying mechanisms by inducing MI in a well-established model of T2DM and control mice. Cardiac imaging revealed a significantly decreased global left ventricular ejection fraction in parallel with increased mortality after MI in T2DM mice compared with control mice. Genome-wide mRNA sequencing, immunoblot, electron microscopy, together with immunofluorescence staining for LC3 and p62 indicated an impaired mitophagy in peri-infarct regions of LV in T2DM mice compared with control mice. Furthermore, defective mitophagy was associated with an increased release of mitochondrial DNA, resulting in Aim2 and NLRC4 inflammasome and caspase-I hyperactivation in cardiomyocytes and cardiac macrophages in peri-infarct regions of LV in T2DM mice. Consistent with inflammasome and caspase-I hyperactivation, cardiomyocyte death and IL-18 secretion were increased in T2DM mice. Our results indicate that T2DM aggravates HF after MI through defective mitophagy, associated exaggerated inflammasome activation, cell death, and IL-18 secretion, suggesting that restoring mitophagy and inhibiting inflammasome activation may serve as novel targets for the prevention and treatment of HF in T2DM. (Am J Pathol 2017, 187: 2659–2673; https://doi.org/10.1016/j.ajpath.2017.08.023)
finally HF. The cellular and molecular pathways contributing to maladaptive ventricle remodeling and HF after MI in diabetic patients are poorly understood, and uncovering the underlying pathophysiological mechanisms may lead to targeted therapies for diabetic patients with MI.

Herein, we have addressed cellular and molecular pathways underlying left ventricular maladaptive remodeling after MI in a well-established mouse model of insulin resistance and T2DM. These mice demonstrate typical features of human T2DM, including insulin resistance, hyperglycemia, and mild hyperinsulinemia. In addition, these mice showed increased atherosclerotic progression and lesion calcification. Previously, with the use of these T2DM mice we have demonstrated an impaired vascular growth in response to hindlimb ischemia as a consequence of altered macrophage phenotype. With the use of transcriptional profiling and molecular characterization, we found an impaired mitophagy in cardiomyocytes from the peri-infarct zone of LV in T2DM mice. In addition, impaired mitophagy was associated with an increased release of mitochondrial-DNA (mtDNA)-derived damage-associated molecular patterns (DAMPs) intracellularly and extracellularly. Thus, impaired mitophagy and subsequent inflammasome hyperactivation were associated with an increased cardiomyocyte death and proinflammatory cytokine secretion (IL-18) that contributed to maladaptive left ventricular remodeling and HF after MI. Modulation of mitophagy together with inhibition of inflammasome activation may offer a novel therapeutic approach for the prevention of HF after MI in T2DM.

Materials and Methods

Mouse Model

Both male and female mice aged between 12 and 14 months were used in the study (12 to 15 mice per group per time point). All animal experiments were approved by the Experimental Animal Committee, University of Eastern Finland, and procedures were conducted in accordance with approved animal protocols. Mice overexpressing IGFII in pancreatic beta cells in hyperlipidemic (LDLR−/−ApoB100/100) background (IGFII/LDLR−/−ApoB100/100) with type 2 diabetic features were fed with high-fat diet for 12 weeks (TD 88173; Boxmeer, NL, 42% of calories from fat and 0.15% from cholesterol, no sodium cholate; Harlan Teklad, Madison, WI), with C57BL/6J mice fed with regular chow-diet (R36; Lactamin, Stockholm, Sweden) serving as controls.

Mouse MI

All mice were randomly selected for MI operations. MI was induced by ligation of the left anterior descending coronary artery (LAD) as described previously. Mice were subjected to small left thoracotomy under general anesthesia with isoflurane (2%). The heart was temporarily exteriorized, and a 0.6 silk suture was placed 2 mm below the origin of the LAD. The heart was replaced immediately into the thoracic cavity, and all thoracic air was evacuated to avoid pneumothorax. Sham operations were performed by passing the suture around the LAD without ligation. After MI, the animals remained supervised until fully conscious. The researcher performing MI operations was blinded for mice groups.

MRI

Functional cardiac parameters were measured by magnetic resonance imaging (MRI) at baseline, day 7, and day 14 after MI. Mice were anesthetized with 1.5% to 2% isoflurane in 70% N2:30% O2 throughout the imaging procedure. A pneumatic pillow placed on the side of the mouse was used for respiratory monitoring and gating the imaging. ECG needles were placed subcutaneously on the mouse front paws to monitor the heart rate and to trigger the imaging. Temperature was maintained at 35°C to keep body temperature constant. Images were acquired on a 7T horizontal-bore Pharmascan (Bruker Biospin, Ettlingen, Germany) with a 38-mm diameter of surface radiofrequency coil. Short-axis of the heart was determined from echocardiography images on three orthogonal planes (transverse, longitudinal, and sagittal). Axial images perpendicular to the long axis were chosen for cine imaging. An orthogonal long-axis slice and a stack of short-axis slices covering the heart from apex to base were acquired using an ECG and respiratory gating with the following parameters: repetition time of 5.2 milliseconds, echocardiography time of 2 milliseconds, slice thickness of 1 mm, matrix size of $192 \times 192$ (in $2.56 \times 2.56 \text{ cm}^2$ field-of-view), and 6 to 8 frames per sequence.

Image Analysis

Image analysis was performed with Aedes (http://aedes.uef.fi, accessed February 12, 2016), on MATLAB (Mathworks Inc., Natwick, CA). Manual segmentation of the endocardium and epicardium of the LV was performed to measure global left ventricular functional parameters [end-diastolic (EDV) and end-systolic (ESV) volume]. Ejection fraction (EF) was calculated using the formula $\text{EF} \% = \frac{\text{[(EDV} - \text{ESV)/EDV]} \times 100$. 

RNA-Sequencing Library Preparation

Total RNA was isolated from cardiac tissue proximal and distal to the LAD ligation using RNeasy Fibrous Tissue Mini Kit (Qiagen Finland, Helsinki, Finland) according to the manufacturer’s instructions. RNA quantity and quality were assessed with Nanodrop. Poly (A)-RNA was selectively enriched with MicroPoly (A) Purist Kit (Ambion,
Austin, TX). RNA was treated with TURBO DNase (Ambion), fragmented using RNA Fragmentation Reagents (Ambion), and purified by running through P-30 column (Bio-Rad, Hercules, CA). Fragmented RNA was dephosphorylated with Antarctic phosphatase (New England Biolabs, Ipswich, MA), followed by heat-inactivation. Dephosphorylation reactions were mixed with 2 × Novex Tris/borate/EDTA (TBE)-Urea sample buffer (Invitrogen, San Diego, CA), briefly denatured, and loaded on a Novex denaturing 15% polyacrylamide TBE-urea gel according to the manufacturer’s instructions. Fragments of 50 to 300 nucleotides in length were gel purified as described previously.16 Following this original protocol, the poly (A)-tailing and cDNA synthesis was performed the next day. However, for reverse transcription oligos with custom barcodes (underlined) were used as follows: S5′-phosCA/TG/AC/GTGA/TGGGACTG/TAAGACTCTTs/dSp/CAAGCAGAAGACGGCATACGATTTTTTTTTTTTTTTTTTTTTTTTTTTTN-3′. After cDNA synthesis, exonuclease was used to catalyze the removal of excess oligos. Enzyme was inactivated, and RNA was hydrolyzed by alkaline treatment (100 mmol/L NaOH) and heat (25 minutes, 95°C). The cDNA fragments of approximately 150 to 200 bps were purified on a Novex denaturing 10% polyacrylamide TBE-urea gel (Invitrogen). The recovered cDNA was circularized, linearized, and amplified for eight cycles. The final product was ran on Novex 10% TBE gel, gel purified as above and cleaned-up using chromatin immunoprecipitation DNA clean & Concentrator Kit (Zymo Research Corporation, Irvine, CA). The library was sequenced for 50 cycles on the Illumina (San Diego, CA) HiSeq 2000 according to the manufacturer’s instructions.

RNA-Sequencing Data Analysis

Single-end sequencing reads were quality controlled with the FastQC software version 0.11.5 (http://www.bioinformatics.babraham.ac.uk/projects/fastqc, last accessed April 2, 2016), and subsequently bases with poor quality scores were trimmed (requiring a minimum 97% of all bases in one read to have a min phred quality score of 10) with the use of the FastX toolkit version 0.0.13 (http://hannonlab.cshl.edu/fastx_toolkit, accessed April 2, 2016). The TopHat software version 2.0.9 (Johns Hopkins University, Baltimore, MD) was used for read alignment to the mouse genome (version mm9), accepting up to two mismatches. A transcriptome index was built from genes.gtf file available from the UCSC mm9 Genomes database (Illumina). The HOMER toolkit version 4.3 (Salk Institute for Biological Studies, La Jolla, CA; http://homer.salk.edu/homer) was used for visualization and transcript quantification based on UCSC Refseq annotations. Transcripts expressed at a level rpkm > 1 in at least three samples were used for statistical analysis with the R/Bioconductor package edgeR. Estimation of dispersion was performed gene-wise using default settings. Differentially expressed transcripts were identified using the glmLRT function. Transcripts with at least 1.5-fold change in expression level and adjusted P < 0.005 (Benjamini-Hochberg method using P values from moderated t-test) were defined significantly regulated.

Functional Analysis

Differentially expressed genes in infarct and peri-infarct regions of LV of T2DM mice compared with control mice were subjected to Ingenuity pathways analysis program (Qiagen, Redwood City, CA). Differentially expressed genes were grouped into functional categories by combining data available in National Center for Biotechnology Information gene information and gene expression data in public data sets.

Histologic Examination

After sacrificing the mice, hearts were perfused with phosphate-buffered saline (PBS) and immersion fixed in 4% paraformaldehyde/15% sucrose (pH 7.4) for 4 hours and then rinsed in 15% sucrose (pH 7.4) overnight. Paraffin-embedded sections (5 μm thick) were cut transversely for immunohistochemistry as mentioned previously.14 Capillaries were stained with rat anti-mouse CD31 (catalog number 550274; dilution 1:50; BD Pharmingen, San Jose, CA.). Capillary density was measured in a blinded manner (T.D.D.) from five different fields from infarct, peri-infarct, and remote zones. Avidin-biotin–horseradish peroxidase system with diaminobenzidine (DAB) color substrate (catalog number PK-6100; Vector Laboratories, Burlingame, CA) was used for signal detection. Collagen content was analyzed from picro-Sirius Red–stained sections. The

percentage of positive stained area was calculated in relation to the whole left ventricular area. Images of stained histologic sections were taken and processed using an Olympus AX 70 microscope (Olympus Optical, Tokyo, Japan) and analySIS version 2.0 (Soft Imaging System, Muenster, Germany) and Photoshop version 11.0.2 (CS4; Adobe, San Jose, CA) softwares. The peri-infarct region within the LV was defined as area containing both infarcted and surviving myocardium within the high power field, whereas the remote region was chosen from a myocardial region without any infarction.

Immunofluorescence Microscopy

All immunofluorescence stainings were performed on paraffin sections. Macrophages were identified using rat anti-mouse F4/80 antibody (catalog number MCA497; dilution 1:50; AbD Serotec, Oxford, UK). M1-macrophages were detected using F4/80 in combination with tumor necrosis factor (TNF)-α antibody (dilution 1:50; catalog number Sc-1351; Santa Cruz Biotechnology, Santa Cruz, CA) and M2-macrophages were detected using F4/80 in combination with arginase I antibody (dilution 1:50; catalog number 387626; AbD Serotec).

Figure 1 Type 2 diabetes mellitus (T2DM) accelerates heart failure and death after myocardial infarction (MI). A: Representative short-axis magnetic resonance images of sham and infarcted mouse hearts. B: Kaplan-Meier survival curves after MI for control (dotted line) and T2DM (thick line) mice 2 weeks after MI. C–E: Quantification of cardiac parameters, including end-diastolic volume (EDV; C), end-systolic volume (ESV; D), and global ejection fraction (E) at baseline and at day 7 and 14 after MI. Data are expressed as means ± SEM (C–E). n = 28 control mice (B); n = 23 T2DM mice (B); n = 5 mice (C–E). Statistical analysis was conducted with one-way analysis of variance with Bonferroni’s multiple comparison test. *P < 0.05, ***P < 0.005 T2DM versus controls, log-rank test.

Figure 2 Transcriptomics analysis reveals cellular alterations associated with heart failure (HF) after myocardial infarction (MI) in type 2 diabetes mellitus (T2DM). A and B: Genome-wide mRNA sequencing analysis of left ventricular tissue at day 7 after MI. With the use of a fold change >1.5 and an adjusted P value of <0.005, 1609 genes were found to be differentially expressed (568 up-regulated and 1041 down-regulated) in the peri-infarct and infarct area of left ventricle (LV) of T2DM mice compared with control mice at day 7 after MI as shown in the scatter plots (A) and volcano plots (B). C: Major biological processes altered in peri-infarct and infarct areas from LV of T2DM mice were identified by the Ingenuity pathway analysis. TCA, tricarboxylic acid.
number Sc-18354; Santa Cruz Biotechnology). Images of stained histologic sections were taken and processed using an Olympus AX 70 microscope (Olympus Optical).

TUNEL Assay for Apoptosis

For in situ detection of apoptosis, terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) assay (In Situ Cell Death Detection Kit, Fluorescein, catalog number 1684795; Boehringer, Mannheim, Germany) was used. Mouse myocardial tissue sections were deparaffinized, digested with Proteinase K, and incubated with TdT and fluorescein-labeled dUTP in a humid atmosphere for 60 minutes at 37°C. After incubation for 30 minutes with an antibody specific for fluorescein-conjugated alkaline phosphatase (Boehringer), the TUNEL stain was visualized with a substrate system in which

nuclei with DNA fragmentation stain green (Fluorescein substrate system; Dako, Carpinteria, CA). Sections were counterstained with a monoclonal antibody specific for sarcomeric actin (catalog number A7811; Sigma-Aldrich, Helsinki, Finland). Tissue sections were examined microscopically at \( \times 400 \) magnification, and TUNEL-positive cells were counted in five high power fields.

**Fourier Transform Infrared Spectroscopic Collagen I Mapping**

Collagen I deposition in remodeled cardiac tissues was detected from 5-μm thick paraffin sections using Perkin Elmer Spotlight 300 spectrometer (PerkinElmer, Shelton, CT). Data acquisition and analysis were performed as described previously.\(^{17}\) The CH\(_2\) side chain vibration (1338 cm\(^{-1}\)) was used to create collagen I distribution images, and the collagen I area in relation to the whole left ventricular area was determined from these images.

**Electron Microscopy**

After scarification and PBS perfusion, left ventricular tissue was quickly cut into 1-mm longitudinal and transverse cubes, immersion fixed in 2.5% glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.4) for overnight at 4°C, and postfixed in 1% buffered osmium tetroxide. The specimens were dehydrated and embedded in LX-112 resin and polymerized. Toluidine blue staining of semi-thin sections were used to evaluate the orientation of the sections. Ultra-thin sections (approximately 70 nm) were double stained with lead citrate and uranyl acetate and visualized with transmission electron microscopy (JEM 1200EX; JEOL Ltd., Tokyo, Japan). Autophagosomes or autolysosomes were identified by the characteristic structure of a double or multilamellar smooth membrane completely surrounding compressed mitochondria or membrane-bound electron-dense material.\(^{18}\)

**Immunelectron Microscopy**

Left ventricular tissues were fixed in 4% paraformaldehyde in 0.1 mol/L phosphate buffer, immersed in 2.3 mol/L sucrose in PBS, and frozen in liquid nitrogen. Cryo-sections were incubated with mouse monoclonal antibody against double-stranded DNA (dsDNA) (catalog number ab27156; Abcam, Cambridge, UK), followed by incubation with 10 nm of gold-conjugated secondary antibody (British Biocell International, Cardiff, UK). Control grids were incubated with the secondary antibody alone or with an irrelevant IgG.

**Flow Cytometric Analysis of Cardiac Macrophages**

Flow cytometry was performed as described previously.\(^{14}\) Infarcted cardiac muscles were minced and enzymatically dissociated using a cocktail that contained 450 U/mL Collagenase I, 125 U/mL Collagenase XI, 60 U/mL DNAsel, and 60 U/mL hyaluronidase (Sigma-Aldrich) for 1 hour at 37°C. The cells were then counted and stained for macrophage antigens after initially blocking with rat anti-mouse CD16/32 mAb (Fc Block; catalog number 553141; BD Pharmingen.) for 10 minutes at 4°C. To identify M2-like macrophages, we performed staining for Cd45 (catalog number 103131; BioLegend, San Diego, CA), F4/80 (MCA497FB; AbD Serotec), and MRC1 (141707; BioLegend). Fluorescence minus one controls were used to analyze the specific stainings. Fluorescence-activated cell sorting (FACS) was performed on FACSaria III (BD Biosciences), and data were analyzed with FCS express 6 (De Novo Software, Glendale, CA).

**Adult Cardiomyocyte Isolation**

Mice were sacrificed by rapid neck disarticulation. The thorax was opened, and the aorta was cannulated. Adult mouse ventricular myocytes were obtained by enzymatic dissociation as previously described (AICS Procedure Protocol PP00000125).\(^{15}\) Briefly, isolated hearts were placed in a Langendorff apparatus for perfusion (37°C, 3 mL/min) with trypsin (Sigma-Aldrich, St. Louis, MO) and liberase (Roche Applied Science, Indianapolis, IN) solution. After perfusion, ventricles were cut into small pieces and gently minced with a Pasteur pipette. The supernatants that contained dissociated cardiomyocytes were filtered through a nylon mesh (100-μm pore size), and the

**Figure 3** Impaired mitophagy in cardiomyocytes from peri-infarct left ventricle (LV) after myocardial infarction (MI) in type 2 diabetes mellitus (T2DM). A: Expression levels of genes critical in mitochondrial fusion machinery and autophagy in peri-infarct and infarcted left ventricles (LVs) of T2DM mice compared with control mice at day 7 after MI. B: Expression levels of genes critical in mitochondrial fusion and autophagy in cardiomyocytes (CMs) and macrophages isolated from peri-infarct and infarct regions of LV at day 7 after MI. C: Western blot analysis of autophagy proteins LC3 and p62 in myocardial homogenates at day 7 after MI. D: Representative electron microscopic images showing an ordered array of myofibers arranged with mitochondria stacked in between them in CMs of control mice. In addition, intramyocellular lipid deposition can be seen in between mitochondria in the LV of T2DM mice at baseline (black arrows), whereas no lipid droplets were observed in similar regions in control mice. Mitophagy activation showing abundant vacuoles/autolysosomes that contain completely degraded mitochondria (yellow arrowheads) in CMs in peri-infarct regions of LV of control mice, whereas CMs from T2DM mice show an increased accumulation of autophagosomes that contain undergoing mitochondria (red arrowheads). Mitochondria undergoing autophagosomal degradation (red boxed areas) are shown at higher magnification (lower panels). E: Immunoelectron microscopy using anti-DNA antibody showing localization in autolysosomes (blue arrowheads). F: Representative immunofluorescence images showing accumulation of autophagosomes within CMs from peri-infarct areas of LV at day 7 after MI. LC3 and p62 are shown in red and sarcomeric actin in green. Data are expressed as means ± SEM (A–C), n = 4 to 5 control mice (A); n = 4 T2DM mice (A); n = 4 for each group (B); n = 4 (C). *p < 0.05 T2DM versus controls; one-way analysis of variance with Bonferroni’s multiple comparison test. Scale bar = 20 μm. Mφ, macrophage; SA, sarcomeric actin.
cardiomyocyte fraction was separated by sedimentation by centrifugation at 100 × g for 1 minute.

Flow-Assisted Cell Sorting of Cardiac Macrophages

Noncardiomyocyte fraction from Langendorff perfusion protocol was subsequently labeled with CD31 magnetic beads and separated into CD31+ and CD31− fractions by using CD31 magnetic bead enrichment (catalog number 130-097-418; Miltenyi Biotec, Cologne, Germany). For macrophage sorting CD31− fraction was incubated for 15 minutes with rat anti-mouse CD16/32 mAb (Fc Block; catalog number 553141; BD Pharmingen) and stained with fluorescein isothiocyanate–conjugated rat anti-mouse F4/80 antibody (catalog number MCA497F; AbD Serotec) for 30 minutes at 4°C. FACS was performed on FACS AriaIII (BD Biosciences, San Jose, CA) as described previously.14

Real-Time Quantitative PCR

Total RNA isolated from cardiac tissue distal to LAD ligation was reverse transcribed to cDNA with the use of Moloney Murine Leukemia Virus Reverse Transcriptase (Fermentas, Helsingin, Finland). First-strand cDNA was synthesized from 1 μg of the extracted RNA in a 20-μL reaction volume with the use of random hexamers (Promega Corporation, Madison, WI) as primers. Total RNA was isolated from cardiomyocytes, and macrophages underwent FACs using Arcturus PicoPure RNA isolation Kit (K600204; Thermo Fisher Scientific, Waltham, MA). First-strand cDNA was synthesized from 100 ng of total RNA in a 20-μL reaction volume as described above. Gene expression analysis was performed with the Step one plus Real-time PCR system with assays on demand (Applied Biosystems, Foster City, CA).

Western Blot Analysis

Left ventricular tissue was homogenized in tissue protein extraction reagent supplemented with protease inhibitors and sodium orthovanadate. The homogenate was centrifuged at 12,000 × g for 5 minutes, and the supernatant was collected for downstream analysis. Total protein concentration was measured with the BCA kit (catalog number 23227; Pierce Biotechnology, Rockford, IL). Total protein (100 μg) was run on 12% precast gels (catalog number 4561043; Bio-Rad) and transferred on to polyvinylidene difluoride membrane. The membrane was blocked with 5% bovine serum albumin in Tris-buffered saline/0.1% Tween 20 (TBST) for 1 hour at room temperature and then probed with rabbit monoclonal LC3 antibody (catalog number 4599; Cell Signaling, Danvers, MA) and rabbit monoclonal p62 antibody (catalog number TA307334; Origene, Rockville, MD) at 4°C overnight. Proteins were detected with horseradish peroxidase–conjugated goat anti-rabbit secondary antibody (catalog number 31460; Thermo Fisher Scientific) in TBST for 1 hour at room temperature, followed by thorough washing with TBST and incubation with enhanced chemiluminescence substrate (catalog number 32106; Pierce Biotechnology).

Statistical Analysis

Results were expressed as means ± SEM. Statistical significance was evaluated with one-way analysis of variance, followed by Bonferroni analysis or by t-test. All statistical analyses, except RNA-sequencing data analysis, were performed with GraphPad Prism software version 5 (GraphPad Software Inc., La Jolla, CA). A P < 0.05 was considered statistically significant.

Results

T2DM Accelerates Heart Failure and Mortality After MI

T2DM mice displayed an increased body weight and plasma insulin and blood glucose levels at baseline. Heart weight-to-body weight ratio was comparable between the groups (Table 1). MI was induced by LAD ligation in control and T2DM mice. In response to MI, a marked increase in the left ventricular chamber dilation was observed in both groups compared with their respective sham controls (Figure 1A). In response to MI, approximately 60% of all T2DM mice died during the 14 days after MI, whereas only 2.8% of mice died in the control group during the same period. No deaths were observed in...
the sham-operated groups (Figure 1B). At baseline conditions, T2DM mice showed a mild yet nonsignificant decline in EDV compared with controls, whereas ESVs were similar in both groups. After MI, both groups showed a significant increase in left ventricular EDV and ESV compared with baseline values. T2DM mice displayed a robust increase in EDV and ESV compared with controls after MI (Figure 1C and D). A significant systolic dysfunction was observed as assessed by left ventricular EF in mice with MI compared with sham controls ($P < 0.005$, MI versus sham). However, systolic dysfunction was exacerbated in T2DM mice compared with controls as exemplified by a significant decline in global left ventricular EF ($P < 0.005$ at day 7 and 14 After MI, T2DM MI versus control MI) (Figure 1E). Collectively, these data indicated that T2DM adversely influenced cardiac function and increased mortality rate in response to MI.

RNA-Sequencing Reveals Dysregulation of Genes Related to Cardiac Contractility, Cell Death, and Metabolism of Nucleic Acids in T2DM Hearts

Because T2DM severely impairs tissue repair after injury, and accumulating evidence has suggested alterations in the inflammation resolution phase of tissue repair, genome-wide mRNA sequencing was performed on peri-infarct and infarct regions of left ventricular tissue collected at day 7 after MI. Left ventricular tissue remote to the infarct region served as an internal control. The RNA-sequencing data have been deposited in National Center for Biotechnology Information Gene Expression Omnibus (http://www.ncbi.nlm.nih.gov/geo; accession number GSE69201). By using a threshold of fold change $>1.5$ and an adjusted $P$ value of $<0.005$, 1609 genes were found to be differentially expressed in the peri-infarct and infarct regions of LV of T2DM compared with controls. Among them, 568 genes...
were up-regulated and 1041 were down-regulated as shown in the scatter plots in Figure 2A, volcano plots in Figure 2B and Supplemental Table S1,20–22 and Supplemental Table S2. Ingenuity functional annotation suggested an increased cell death, necrosis, movement disorders, heart disease, neuromuscular disease, hypertrophy, and cardiomyopathy, and decreased metabolism of nucleic acid components, metabolism of nucleotides, heart rate, and contractility of muscles in T2DM mice compared with controls as shown in Table 2, Supplemental Table S1,20–22 and Supplemental Table S3. Ingenuity pathways analysis revealed mitochondrial dysfunction, tricarboxylic acid (TCA) cycle, and fatty acid β-oxidation as the most prominent pathways affected by T2DM in the LV after MI as shown in Figure 2C and Supplemental Table S4. Ingenuity upstream regulator analysis suggested an inhibition of peroxisome proliferator-activated receptor γ coactivator (PGC)-1α regulatory network (essential regulator of cardiac metabolism and mitochondrial homeostasis) consisting of coregulators PGC-1α and PGC-1β; nuclear receptors ESRRA, ESRRG, PPARα, PPARγ, PPARδ; other transcription factors TFAM, HAND2, GATA4; and activation of STAT1, NR3C2, NRE1, SMAD3, IRF3, NFATC2, SPI1 in T2DM mice compared with controls as shown in Table 3 and Supplemental Table S5. Collectively, these data reveal that T2DM dysregulates genes important in cardiac function, mitochondrial homeostasis, cell death, and metabolism of nucleic acids in LV after MI.

**Impaired Mitophagy in Cardiomyocytes of Peri-Infarct Region in T2DM Hearts**

Genes critical in mitochondrial fusion machinery and regeneration of healthy mitochondria, including Mfn1, Mfn2, Opal, and genes involved in removal of damaged mitochondria and autophagy, including, Lc3a and Pink1, were significantly down-regulated in peri-infarct regions of LV of T2DM mice compared with controls at day 7 after MI (Figure 3A, Supplemental Table S1,20–22 and Supplemental Table S2). To unravel cell specificity of differential gene expression, we isolated cardiomyocytes from peri-infarct...
and infarct regions using Langendorff perfusion procedure. Subsequently, noncardiomyocyte fractions were used for cardiac macrophage isolation by using a combination of magnetic-assisted cell sorting with FACS. Cell-specific gene expression showed decreased activity of mitochondrial fission and autophagy-related genes predominantly in cardiomyocytes from peri-infarct regions of LV of T2DM compared with controls (Figure 3B). In addition, Western blot analysis showed increased LC3-II/I ratio and p62 levels in left ventricular homogenates from T2DM mice compared with controls, indicating impaired mitophagy/autophagy (Figure 3C). Electron microscopic images showed an ordered array of myofibers arranged with mitochondria stacked in between them in cardiomyocytes of control mice. In addition, intramyocellular lipid deposition was seen in between mitochondria in the T2DM mice at baseline, similar to observations in diabetic human hearts. Mitophagy was activated in the peri-infarct regions of LV of both groups at day 7 after MI. Of interest, cardiomyocytes in peri-infarct regions of LV in T2DM showed increased accumulation of undegraded mitochondria in autophagosomes (Figure 3D). Immunoelectron microscopic analysis with anti-DNA antibody showed localization in autolysosomes, suggesting the release of undegraded mtDNA into cytosol as a consequence of impaired autolysosomal degradation (Figure 3E). Interestingly, our RNA-sequencing analysis suggested decreased metabolism of nucleic acids and nucleotides in LV of T2DM mice, corroborating with impaired mitophagy. In addition, immunofluorescence staining showed increased accumulation of LC3-positive mitophagosomes/autophagosomes, together with increased p62 levels in peri-infarct regions of LV in T2DM mice compared with controls, further suggesting impaired mitophagy/autophagy as a potential mechanism of release of mitochondrial-derived DAMPs intracellularly and extracellularly after cell death (Figure 3F).

Exaggerated Inflammasome Activation and Caspase-I Activity in T2DM Hearts

Genes involved in cytosolic dsDNA sensing (Ifi204, pyhin1), inflammasome (Aim2, NLRC4) and caspase-I were significantly up-regulated in peri-infarct and infarct regions of LV in T2DM mice compared with controls at day 7 after MI (Figure 4A, Supplemental Table S1,20–22 Supplemental Table S2). To dissect out the cell-specific roles of inflammasome in cardiomyocytes and macrophages, these cell populations were isolated, and Pyhin1, Ifi204, Aim2, NLRC4, Eif2ak2, and Caspase-1 were looked at for gene expression. Of note, all these genes were significantly up-regulated both in cardiomyocytes (except Eif2ak2) and macrophages isolated from T2DM mice compared with controls (Figure 4B). Furthermore, immunofluorescence double stainings for cardiomyocyte- and macrophage-specific dsDNA sensors (Pyhin1, Ifi204) showed increased activation both in cardiomyocytes and macrophages from peri-infarct and infarct regions of LV in T2DM compared with controls at day 7 after MI (Supplemental Figure S1). Similarly, immunofluorescence double stainings for cardiomyocyte- and macrophage-specific inflammasome (Aim2, NLRC4) showed abundance of double-positive cells in peri-infarct and infarct regions of LV in T2DM compared with controls at day 7 after MI (Figure 4, C and D).

Inflammasome activation culminates in either caspase-I–mediated cell death (pyroptosis) or cytokine processing into mature active forms (IL-1β, IL-18). To understand the consequence of inflammasome activation in this context, caspase-I activity was examined by immunostainings of left ventricular tissue collected at day 7 after MI. Similar to Aim2 and NLRC4 stainings, caspase-1 immunostaining showed increased activation in peri-infarct and infarct regions of LV in both groups (Figure 4E). In addition, caspase-1 colorimetric assay using left ventricular tissue homogenates showed increased activity in T2DM mice compared with controls (Figure 4G). Next, cell death was examined with TUNEL assay, similar to caspase-1 stainings an increased number of TUNEL-positive cells were observed in peri-infarct and infarct regions of LV of T2DM mice compared with controls (Figure 4, F and H). In parallel with increased inflammasome and caspase-I activity, increased caspase-1–dependent inflammatory mediator (IL-18) was observed in circulation of T2DM mice compared with controls at baseline and day 7 after MI (Figure 4I). Of note, increased inflammation as evidenced by increased IL-18, TNF-α, and circulating immune cells were shown to associate with remodeling and HF after MI in patients. Collectively, these results indicated that exaggerated activation of Aim2 and NLRC4 inflammasome and subsequent increase in caspase-I–mediated pathways in cardiomyocytes and macrophages in peri-infarct and infarct regions of LV of T2DM mice compared with controls.

Altered Cardiac Macrophage Phenotypic Responses in T2DM Hearts

Double immunofluorescence staining of left ventricular tissue for M2-like macrophage (anti-F4/80 and anti–Arginase-1) showed decreased numbers of M2-like macrophages in peri-infarct and infarct regions in LV of T2DM mice compared with controls. On the contrary, stainings for M1-like macrophage (anti-F4/80 and anti–TNF-α) showed an increase in T2DM mice compared with controls at day 7 after MI (Figure 5A). Furthermore, flow cytometric analysis was performed for M2-like macrophages in left ventricular tissues collected at day 7 after MI as described previously. CD45+ F4/80+CD206+ M2-like macrophages were analyzed from sham and infarcted hearts of control and T2DM mice (Figure 5B). Quantification suggested a significant decline in M2-like macrophages in LV of T2DM mice compared with controls.
Collectively, these results indicated an altered macrophage phenotypic response to MI in LV of T2DM mice, consistent with exaggerated inflammasome activation.

Impaired Neovascularization and Increased Fibrosis in T2DM Hearts

Neovascularization responses after MI were examined with capillary endothelial staining with CD31 (CD31+ cells). Quantification of CD31+ cells showed a significantly decreased number of capillaries in peri-infarct and infarct regions of LV in T2DM mice compared with controls at day 7 and 14 after MI (Figure 6, A and B). Corroborating with altered macrophage phenotype, capillary stainings demonstrated an impaired neovascularization after MI in LV of T2DM mice compared with controls.

Infarct size and myocardial fibrosis were evaluated with Sirius Red staining and Fourier transform infrared spectroscopic mapping of collagen-I at baseline and day 14 after MI (Figure 6C). Interestingly, Sirius Red staining and Collagen-I mapping by Fourier transform infrared spectroscopy showed similar patterns of collagen distribution in LVs of both control and T2DM mice. Quantification showed significantly increased area of infarction and collagen-I deposition, especially in LV of T2DM mice compared with controls (Figure 6D). Increased fibrosis has been suggested to disrupt the excitation-contraction coupling between cardiomyocytes, and a subsequent increase in stiffness will lead to decreased ventricular wall compliance, resulting in both systolic and diastolic dysfunction.25 Thus, impaired neovascularization responses coupled with increased fibrosis after MI might further decrease cardiac contractility and left ventricular EF of the heart after MI in T2DM mice compared with controls.

Discussion

In our previous study, we characterized a mouse model of insulin resistance and T2DM, which demonstrates typical features of human T2DM, including insulin resistance, hyperglycemia, and mild hyperinsulinemia.13 In addition, these mice show an increased atherosclerotic progression and lesion calcification. Recently, with the use of these T2DM mice we have demonstrated an impaired vascular growth in response to hindlimb ischemia as a consequence of altered macrophage phenotype.14 In the present study, we provide insights into pathways underlying accelerated HF after MI in T2DM. Transcriptional profiling revealed an increased cell death, necrosis, myocardial dysfunction and decreased heart rate, cardiac contractility, and metabolism of nucleic acids. Integrating transcriptomics and molecular characterization, we show an impaired mitophagy associated with increased accumulation of undegraded mitochondria in autophagosomes in cardiomyocytes from peri-infarct regions of the LV. Furthermore, our immunogold labeling studies suggested localization of mtDNA to autolysosomes in cardiomyocytes of LV, indicating increased release of degraded mtDNA into cytosol as a result of impaired autolysosomal degradation of dysfunctional mitochondria. Reflecting increased cytosolic mtDNA as a result of impaired mitophagy, cytoplasmic DNA sensors, including Pyhin1, Ifi204, and inflammasome, namely AIM2, NLRC4, and Caspase-I, were highly activated in cardiomyocytes and macrophages in peri-infarct and infarct regions of the LV. This was associated with increased cell death and IL-18 secretion, thus linking defective mitophagy to inflammasome activation (Supplemental Figure S2). Moreover, cardiac macrophages showed an altered phenotype consistent with inflammasome activation in LV of T2DM mice.

Mitophagy is a selective form of autophagy involved in the removal of damaged mitochondria during cellular stress, which prevents the release of mitochondria-derived DAMPs to the cytoplasm. In addition, mitophagy prevents activation of prodeath pathways in favor of adaptation to stress.26 We observed an increased number of autophagosomes that contained undegraded mitochondria (mitophagy) but reduced amounts of autolysosomes in cardiomyocytes from peri-infarct regions of LV in T2DM mice together with an increased LC3-II-to-LC3-I ratio and p62 levels. Furthermore, immunofluorescence staining showed an increased accumulation of LC3-positive mitophagosomes/autophagosomes, together with increased p62 levels, further suggesting impaired mitophagy. Given the abundance of mitochondria in cardiomyocytes, it is likely that a substantial amount of mitochondrial DNA would be released extracellularly in the heart on tissue damage as a result of impaired mitophagy.27 Consistent with this notion, immunoelectron microscopic analysis with anti-DNA antibody showed localization in autolysosomes. In addition, our RNA sequencing analysis suggested decreased metabolism of nucleic acids and nucleotides in LV of T2DM, supporting the notion that impaired degradation of mtDNA as a result of insufficient mitophagy might lead to increased release of undegraded mtDNA. Thus, impaired mitophagy-associated DAMPs likely contribute to exaggerated inflammasome activation and cell death. Our observations are in line with a recent study that found increased inflammation and cardiac dysfunction in response to transaortic constriction, as a result of mtDNA release from inefficient degradation by autophagy.28

Inflammasome is a multiprotein complex that activates Caspase-1, triggering an inflammatory cell death called pyroptosis. In addition, caspase-1 triggers the maturation and release of proinflammatory cytokines IL-1β and IL-18.29 Indeed, inflammasome activation in the infiltrated inflammatory cells are shown to enhance myocardial ischemia-reperfusion injury. Of interest, almost all cardiac
macrophages expressed inflammasome adaptor apoptosis-associated speck-like protein containing C-terminal caspase recruitment domain (ASC), whereas approximately 60% of neutrophils expressed ASC. The expression of caspase-1 was visualized mainly in the infiltrated cells of the ischemic myocardium.30 NLRP3 inflammasome activation in cardiomyocytes and cardiac leukocytes in response to ATP released from dying cells was shown to play an important role in adverse cardiac remodeling in response to MI under nondiabetic conditions.31 Thus, inflammasome-dependent caspase-1 activation and subsequent release of IL-18 and IL-1β, both in cardiomyocytes and macrophages, seems to lead to HF. Accordingly, inhibition of caspase-1 reduced cardiomyocyte death, improved cardiac function, and significantly decreased rates of mortality.32–34 Transgenic mice overexpressing caspase-1 show an increased cardiomyocyte cell death and HF after MI, independent of increase in IL-1β and IL-18 secretion.35 Collectively, our findings suggest that defective mitophagy in T2DM contributes to HF after MI through exaggerated inflammasome activation, subsequent cell death, and cytokine secretion.

Our results suggest an increased inflammasome activation in cardiac macrophages from T2DM mice compared with control mice. In parallel, immunofluorescence stainings and flow cytometric analysis suggested a decrease in reparative M2-like macrophages but an increase in inflammatory M1-like macrophages in LV of T2DM mice. Consistent with altered macrophage phenotype, T2DM displayed impaired neovascularization and increased fibrosis in peri-infarct and infarct regions in the LV at day 14 after MI. Although both M1- and M2-macrophages are critical for resolving myocardial injury, it has become increasingly evident that shifting the balance of macrophage to an M2-like phenotype is cardioprotective.36,37 On the contrary, the delayed phenotypic transition of M1-like macrophages to M2-like macrophages and/or prolonged and increased recruitment of inflammatory monocytes to the heart leads to impaired infarct healing and increased HF after MI as demonstrated in atherosclerotic mice.37,38 In line with these observations, we found skewing of cardiac macrophages toward a proinflammatory phenotype in T2DM hearts, associated with impaired neovascularization and increased fibrosis compared with reparative macrophage phenotype in control hearts.

We recognize that our study has limitations. Comparisons were made between T2DM mice with C57BL/6J controls to keep all mice on the same genetic background which can have significant effects on the measured variables. In addition, aged mice with high-fat diet were used to aggravate the T2DM phenotype.13 However, we cannot exclude a possibility that other factors such as age, insulin resistance, or high-fat diet could have contributed to the observed differences in response to MI. Despite these limitations, our findings suggest that T2DM significantly contributed to aggravated post-infarct HF.

Conclusions

Our results suggest that an impaired mitophagy and exaggerated inflammasome activation together with altered macrophage phenotypic responses may contribute to HF after MI in T2DM. Modulation of mitophagy together with inhibition of inflammasome activation may offer a novel therapeutic target.
