The genitourinary syndrome of menopause has a negative impact on quality of life of postmenopausal women. The treatment of vulvovaginal atrophy includes administration of estrogens. However, oral estrogen treatment is controversial because of its potential risks on venous thrombosis and breast cancer. Estetrol (E4) is a natural estrogen synthesized exclusively during pregnancy by the human fetal liver and initially considered as a weak estrogen. However, E4 was recently evaluated in phase 1 to 2 clinical studies and found to act as an oral contraceptive in combination with a progestin, without increasing the level of coagulation factors. We recently showed that E4 stimulates uterine epithelial proliferation through nuclear estrogen receptor (ER) α, but failed to elicit endothelial responses. Herein, we first evaluated the morphological and functional impacts of E4 on the vagina of ovariectomized mice, and we determined the molecular mechanism mediating these effects. Vaginal epithelial proliferation and lubrication after stimulation were found to increase after E4 chronic treatment. Using a combination of pharmacological and genetic approaches, we demonstrated that these E4 effects on the vagina are mediated by nuclear ERα activation. Altogether, we demonstrate that the selective activation of nuclear ERα is both necessary and sufficient to elicit functional and structural effects on the vagina, and therefore E4 appears promising as a therapeutic option to improve vulvovaginal atrophy. (Am J Pathol 2017, 187: 2499–2507; http://dx.doi.org/10.1016/j.ajpath.2017.07.013)
innovative therapies. Selective estrogen receptor (ER) modulators are compounds characterized by specific tissue-selective actions, being agonists and mimicking some effects of estrogens while antagonizing others. An ideal selective ER modulator would preserve the beneficial effects of estrogens on the bone and urogenital system, and reduce their unwanted adverse effects, mainly increased risk of venous thrombosis and of breast cancer. Recent studies suggest that estetrol (E4) should be considered as an interesting candidate. Although discovered as early as 1965, E4 was considered during several decades as a weak estrogen produced only by the human fetal liver during pregnancy. E4 was recently evaluated in phase 1 to 2 clinical studies and was found to have a good potential as an oral contraceptive when it was combined with a progestin in fertile women. E4 was also efficient in preventing hot flushes in an experimental animal model. Previous animal and human studies indicate that E4 has estrogenic effects on ovariecotimized rats and on the vaginas of postmenopausal women. The potency of E4 is approximately 20-fold lower compared to ethinyl estradiol for the rat. In women, trogens while antagonizing others. An ideal selective ER modulator would preserve the beneficial effects of estrogens on the bone and urogenital system, and reduce their unwanted adverse effects, mainly increased risk of venous thrombosis and of breast cancer. Recent studies suggest that estetrol (E4) should be considered as an interesting candidate. The biological effects of estrogens are mediated by their binding to the two ERs (ERα and ERβ), leading to conformational changes, dimerization, and recruitment of coactivators into the nucleus, where they interact with estrogen response elements or other transcription factors to modulate the transcription of target genes. Ligand-induced transcriptional activity of ER involves the action of two distinct activation functions (AFs), AF1 and AF2. The time lag between estrogen administration and observable transcriptional effects is typically in the order of hours to days. However, in addition to the nuclear (alias genomic) actions of ER, estrogens have been found to induce rapid effects occurring within minutes after administration. These effects are mediated through a subpopulation of receptors associated with the plasma membrane, a process usually termed membrane-initiated steroid signaling. A knock-in mouse model was recently generated by mutating the cysteine 451 palmitoylation site of ERα to alanine (designated C451A-ERα), which provides a specific loss of function of membrane ERα. A mouse model for selective loss of function of nuclear ERα actions is also available, obtained after inactivation of AF2, consisting of a deletion of the amino acids 543 to 549 in the helix 12 of ERα (designated ERα AF20). Using combined genetic and pharmacological approaches, we proposed that E4 modulates ER actions in a tissue-specific manner through a selective nuclear, but not membrane, ERα activation. Thus, E4 should now be considered not as a weak estrogen, but rather as a selective ER modulator.

The aim of this study was to evaluate the morphological and functional impacts of E4 on the vagina of ovariectomized mice and to determine the molecular mechanisms mediating these effects. We showed that, in ovariectomized mice, E4 chronic treatment increased vaginal epithelial proliferation and vaginal lubrication after stimulation. Using a combination of pharmacological and genetic approaches, we demonstrate that these effects of E4 are mediated by nuclear ERα activation.

### Materials and Methods

#### Mice

Procedures were performed in accordance with the recommendations of the European Accreditation of Laboratory Animal Care and the guidelines established by the National Institute of Medical Research (INSERM). Female C57BL/6J mice were purchased from Charles River (Malvern, PA). Mice targeted for ERα, ERβ, ERα-AF2, and C451A-ERα mice have been previously described.

Mice were anesthetized by injection of ketamine (25 mg/kg) and xylazine (10 mg/kg) in an i.p. route, ovariecotimized or sham-operated at 4 weeks of age, and implanted, 3 weeks later, subcutaneously with 17β-estradiol (E2) pellets (8 or 80 μg/kg per day, 60-day release; Innovative Research of America, Sarasota, FL), E2 minipumps (6 or 1 mg/kg per day, 28-day release; Alzet Durect Corp., Cupertino, CA), estrogen-dendrimer conjugate (EDC; 240 μg/kg per day), or empty dendrimer at a rate identical to that delivered with EDC as a control. EDC selectively activates ER membrane signaling. EDC was kindly provided by Sung Hoon Kim, John A. Katzenellenbogen, and Benita S. Katzenellenbogen (University of Illinois at Urbana–Champaign). Animals were euthanized after a 3-week treatment period. E2 doses of 8 and 80 μg/kg per day have been previously reported, to elicit a circulating plasma E2 level in the high range of the mouse estrous cycle and in pregnant mouse, respectively.

Mice received two doses of E4 (1 or 6 mg/kg per day; ie, 25 or 150 μg/day per animal), in line with multiple in vivo animal and human data that show that human therapeutic equivalence of E4 in comparison to E2 requires a 3- to 15-fold higher dose. In addition, such E4 doses induce steady-state plasma levels of E4 equivalent to those found in women exposed to therapeutic doses (2.5 to 15 mg) of E4 and to those found in the plasma of term fetuses.

#### Cervical Vaginal Lubrication

Cervical vaginal lubrication was evaluated in ovariecotimized mice either left untreated or treated with E2, E4, or EDC, as

---

**Benoit et al**

---

**2500**
previously described.\textsuperscript{31} Under anesthesia, the vagina was stimulated by five strokes within 5 seconds against the cervix by a 3 French (1.0-mm wide) Teflon-coated probe inserted into the vaginal lumen (3 French occlusion balloon catheter; Coloplast, Rosny-sous-Bois, France). One minute after the stimulation, a preweighed absorbent paper strip was inserted into the vagina for 10 seconds. Vaginal lubricate volume was calculated using the difference in the paper weights (in milligrams) after and before insertion (Mettler AC 100 analytical balance; Mettler Toledo, Viroflay, France).

Histological Analysis, Immunohistochemistry, and Histomorphometry

Mice were euthanized for histological analysis at 10 weeks of age after a 3-week treatment. Paraffin-embedded transverse sections (4 μm thick) from formalin-fixed vagina specimens were stained, as previously described,\textsuperscript{32} using the anti–Ki-67 (RM-9106; Thermo Fisher Scientific, Waltham, MA) and the anti-ER\(\alpha\) (MC-20; Santa Cruz Biotechnology, Dallas, TX) antibodies. Images of whole vagina sections were acquired using a NanoZoomer Digital Pathology Scanner (Hamamatsu Photonics, Shizuoka, Japan). To examine the proliferative effect of each treatment, the ratio of Ki-67–positive epithelial/total cell number was evaluated in each vaginal section after two quantifications at \(\times 20\) magnification. The luminal epithelial height was measured from the basal membrane to the apical surface, as described previously in the uterus.\textsuperscript{32} Briefly, the values of the epithelial height are the mean of 10 measurements in two transverse vaginal sections of each specimen.

Protein Extraction and Western Blot Analysis

Vagina specimens were removed en bloc, rinsed with ice-cold saline buffer, frozen by immersion in liquid nitrogen, and stored at \(-80^\circ\text{C}\). Total proteins from vagina were separated on a 10% SDS/PAGE gel and transferred to a nitrocellulose membrane. The membranes were then incubated with the primary monoclonal anti-ER\(\alpha\) (60C; Millipore, Billerica, MA) and polyclonal anti–β-actin (A2066; Sigma, St. Louis, MO) antibodies. Subsequently, blots were incubated with a horse-radish peroxidase–conjugated secondary antibody (SC2030; Santa Cruz Biotechnology) and visualized by electrochemiluminescence detection, according to the manufacturer’s instructions (Amersham Biosciences, Piscataway, NJ), using a ChemiDoc Imaging System (Bio Rad Laboratories, Hercules, CA). Bands corresponding to ER\(\alpha\) and β-actin were quantified using ImageJ software version 1.45S (NIH, Bethesda, MD; \text{http://imagej.nih.gov/ij\}) densitometry, and the ratio of the band intensities was calculated.

Analysis of mRNA Levels by Real-Time Quantitative PCR

Vaginas were homogenized using a Precellys tissue homogenizer (Bertin Technology, Montigny-le-Bretonneux, France), and total RNA from tissues was prepared using TRIzol reagent (Invitrogen, Carlsbad, CA). RNA was reverse transcribed using the High Capacity cDNA Reverse Transcriptase Kit (Applied Biosystems, Villebon sur Yvette, France). Real-time quantitative PCRs were performed on the StepOne instrument (Applied Biosystems). Primers were validated by testing PCR efficiency using standard curves (95% ≤ efficiency ≤105%). Gene expression was quantified using the comparative \(C_T\) method; hypoxanthine guanine phosphoribosyl transferase 1 was used as a reference.

Statistical Analysis

Results are expressed as means ± SDs or SEMs, as indicated. The effect of hormonal treatments and the genotypes were tested with a one- or two-factor analysis of variance model for repeated measurements, followed by pairwise comparisons with the Bonferroni post hoc test using Prism software version 5.1 (GraphPad Software, Inc., La Jolla, CA). \(P < 0.05\) was considered statistically significant.

Results

E4 Induces Morphological Changes in the Vagina and Increases Vaginal Lubrication

We previously showed that E4, a natural estrogen with four hydroxy groups (Figure 1A), is less potent than E2 to activate ER\(\alpha\), but a 100-fold higher dose is able to modulate the transcriptional activity of ER\(\alpha\) in the uterus as well as the proliferation of endometrial epithelium.\textsuperscript{26} To evaluate E4 effect on the vagina, mice were treated chronically with E2 (8 and 80 μg/kg per day) and E4 (1 and 6 mg/kg per day). E2 and E4 induced a similar increase in vaginal weight (E2, 80 μg/kg per day versus ovariectomized: 135.1 ± 10.2 versus 29.5 ± 4.5 mg; and E4, 6 mg/kg per day versus vehicle: 124.3 ± 12.1 versus 36.5 ± 12.1 mg; both \(P < 0.0001\)), whatever the dose of estrogen compounds (Figure 1, B and C).

Histological analysis of the vagina revealed similar change in response to E2 or E4. Epithelium of ovariectomized mice was composed of only two cellular layers, and E2 or E4 treatments at both doses induced a large expansion of these cellular layers (Figure 1D). Both treatments similarly increase the epithelial height in comparison to untreated ovariectomized mice (Figure 1E). In addition, epithelial proliferation was evaluated by immunohistochemical detection of Ki-67 antigen. The percentages of cells that were positively stained with Ki-67 antibody were 38.9% ± 7.3% for E2-treated mice and 30.5% ± 6.1% for E4-treated mice (ie, similarly increased compared to untreated mice) (Figure 1E).

The vaginal lubrication was further measured to investigate the functional consequences of these hormonal treatments. Vaginal lubrication after cervical vaginal stimulation was significantly increased in E2- and E4-treated mice.
compared to untreated mice (Figure 2), with no difference between E4 and E2 treatment, whatever the dose. Altogether, this demonstrates a similar morphological and functional impact of chronic E2 and E4 on the vagina of ovariectomized mice.

Vaginal ERα Expression and Role of ERα in the Effect of E4

The respective roles of ERα and ERβ in the effects of E4 treatment at the dose of 6 mg/kg per day were studied using
was associated with a marked decrease of ERα mRNA abundance (Figure 3C). Taken together, these results demonstrated that both chronic E2 and E4 treatment led to a pronounced decrease in ERα expression in the vagina of mice.

The Effects of E2 and E4 on the Vagina of Mice Are Mediated by Nuclear ERα Activation

A pharmacological approach was used to test the contribution of membrane ERα on the effect of estrogens on the vagina using an EDC that selectively activates ER membrane signaling (Figure 4A). The EDC has a high chemical stability, is free from traces of unattached ligand, and is specific in stimulating nongenomic responses.38,39 Chronic EDC treatment of ovariectomized mice did not alter epithelial height or vaginal lubrication (Figure 4B). These results indicate that selective membrane ERα activation is not sufficient to elicit an action on vagina.

To further analyze the role of membrane versus nuclear ERα activation in the effects of E4, a genetic approach was used. Mice lacking the ERα activation function AF2 (ERα AF2b) provide a selective loss of function of nuclear ERα actions. We first evaluated the effect of a chronic treatment of E4 on the vagina from ERα AF2b mice. Results showed that the vaginal response to E4 was completely abolished in ERα AF2b mice, whereas, as expected, the morphological and functional responses were normal in the wild-type littermates (Figure 4C). Conversely, mice with an inactivation of membrane ERα (C451A) did not reveal any detectable alteration in the E4 action on the vagina structure or lubrication compared to wild-type mice (Figure 4D). These data indicate that selective activation of nuclear ERα is both necessary and sufficient to elicit morphological and functional benefits of E4 on the vagina.

Discussion

E4 is a natural estrogen with four hydroxyl groups produced exclusively during pregnancy by the human fetal liver.15 This steroid is detected in maternal plasma and urine during pregnancy; it also exhibits weak estrogenic agonist

effects on the uterus.26,34 Clinical data obtained from a phase 2 clinical trial show that E4 has a lower impact on coagulation than 17—beta-estradiol or E2 and, thus, might have minimal impact on thromboembolic events.21 Moreover, recent studies reported that E4 has interesting properties on breast tissue,35,36 and we sought herein to evaluate extensively its effects on the vagina. We demonstrate that a chronic E4 treatment has a morphological and functional impact on the vagina of mice similar to that elicited by E2. Furthermore, we show that nuclear ER activation is both necessary and sufficient to mediate these effects, whereas membrane ER is fully dispensable.

We have first demonstrated that ovariectomized mice treated with E4 (1 or 6 mg/kg per day) had an increased vaginal epithelial thickness. Consistently, Heegaard et al19 also reported a higher cornification in rats treated by E4. We report that the higher epithelial thickness elicited by E4 was secondary to a higher epithelial cell proliferation. This impact on epithelial length is of clinical interest because the decreased thickness and elasticity of the epithelial wall, followed by the exposition of the sensory nerve fibers of the stroma, are part of the mechanisms that explain dyspareunia.37,38 Thus, a normal epithelial wall may protect the vagina from trauma during coitus, and glycoprotein production is necessary for normal vaginal lubrication.39 Moreover, mice treated with E4 revealed an increased lubrication. Similarly, Kim et al40 found that ovariectomy led to a decrease of vaginal secretion compared to the control group, and E2 treatment restored the amount of vaginal secretion in ovariectomized rats.

This study showed, for the first time, that both E2 and E4 effects on the vagina are mediated through ERα and not ERβ.41 Both localizations within the vagina are important because E2-induced epithelial proliferation is mediated indirectly through stromal ERα, in the vagina42 and in the uteri.43 These results suggest the importance of stromal-epithelial interactions in the reproductive tissues, but the nature of these paracrine events and how they are modified by estrogens are unknown. Further studies could evaluate the different roles of stromal and epithelial ERα in E4-induced vaginal proliferation, cornification, and stratification. In addition, we found that the decrease of the protein level of ERα was secondary to a down-regulation of ERα gene expression. Thus, the effect of E4 on ERα protein level was not secondary to a destruction, but to a decrease of ERα transcription.

Estrogens exert biological effects through activation of nuclear ERα, but a subset of membrane ERα, leading to

membrane-initiated steroid signaling, was recently shown to play an important physiological role in fertility, bone, and endothelium.\textsuperscript{24,43} In the present study, we used the combination of pharmacological and genetic approaches to determine the respective roles of membrane and nuclear ER\textsubscript{a} in the effect of E4 on the vagina. We first showed that mice treated by EDC, a selective agonist of the membrane ER\textsubscript{a} or the vehicle, did not reveal any morphological or functional vaginal response, demonstrating that the activation of membrane ER\textsubscript{a} is not sufficient to mediate the effects of E4 on the vagina. We then explored the respective role of membrane and nuclear ER\textsubscript{a} using mutated mice. C451-ER\textsubscript{a} mice presented the same favorable effect of E4 versus littermate mice. Altogether, membrane ER\textsubscript{a} activation is neither sufficient nor necessary to mediate the effect of estrogens in the vagina. Using ER\textsubscript{a} AF20, we showed that nuclear ER\textsubscript{a} activation is absolutely necessary for E4 actions on the vagina.

These results have to be confirmed by phase 2 clinical studies with E4 orally given or locally applied. In addition, phase 2 and 3 trials need to document clinical effects on breast, bone, uterus, brain, and venous thromboembolism risk as well as sleep disturbances and vasomotor symptoms caused by the lack of estrogen during menopause.

\end{figure}
Conclusion

Symptoms of VVA represent a major health problem, concerning approximately 50% of women during and after menopause, and lead to a decrease of sexual activity and quality of life. Actually, E2 treatments decrease these symptoms, but their use is restricted by several adverse effects. We show herein that E4, a natural estrogen, is able to stimulate proliferation of the epithelium and to improve the function (lubrication) of the murine vagina. Furthermore, we demonstrated that the E4 action on this tissue can be entirely explained by its selective nuclear activation of ERz, accounting for its efficiency similar to E2 in this sex target. Clinical studies are needed to confirm this important potential of E4 for the treatment of menopausal symptoms.

Acknowledgments

We thank the staff of the animal facilities and of the Functional Experimentation Platform for skillful technical assistance; and Marie-José Fouque, Guy Carcasses, Jean-Jose Maoret, and Frederic Martins for their excellent technical assistance and contribution to real-time quantitative PCR experiments performed at the GeT-TQ Genopole Toulouse Facility. EDC was kindly provided by Sung Hoon Kim, John A. Katzenellenbogen, and Benita S. Katzenellenbogen (University of Illinois at Urbana–Champaign).

T.B. is the guarantor of this work and, as such, had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.
