Tumor immune microenvironment and tumor metabolism are major determinants of chemoradiotherapy response. The interdependency and prognostic significance of specific immune and metabolic phenotypes in head and neck squamous cell carcinoma (HNSCC) were assessed and changes in reactive oxygen species were evaluated as a mechanism of treatment response in tumor spheroid/immunocyte co-cultures. Pretreatment tumor biopsies were immunohistochemically characterized in 73 HNSCC patients treated by definitive chemoradiotherapy and correlated with survival. The prognostic significance of CD8A, GLUT1, and COX5B gene expression was analyzed within The Cancer Genome Atlas database. HNSCC spheroids were co-cultured in vitro with peripheral blood mononuclear cells (PBMCs) in the presence of the glycolysis inhibitor 2-deoxyglucose and radiation treatment followed by PBMC chemotaxis determination via fluorescence microscopy. In the chemoradiotherapy-treated HNSCC cohort, mitochondrial-rich (COX5B) metabolism correlated with increased and glucose-dependent (GLUT1) metabolism with decreased intratumoral CD8/CD4 ratios. High CD8/CD4, together with mitochondrial-rich or glucose-independent metabolism, was associated with improved short-term survival. The Cancer Genome Atlas analysis confirmed that patients with a favorable immune and metabolic gene signature (high CD8A, high COX5B, low GLUT1) had improved short- and long-term survival. In vitro, 2-deoxyglucose and radiation synergistically up-regulated reactive oxygen species—dependent PBMC chemotaxis to HNSCC spheroids. These results suggest that glucose-independent tumor metabolism is associated with CD8-dominant antitumor immune infiltrate, and together, these contribute to improved chemoradiotherapy response in HNSCC. (Am J Pathol 2018, 188: 72–83; https://doi.org/10.1016/j.ajpath.2017.09.013)

Head and neck squamous cell carcinoma (HNSCC) is the fourth most common cancer in the United States with almost 62,000 new cases per year. Although either single-modality surgery or radiotherapy is often used for early (stage I to II) disease, chemoradiotherapy (CRT) is frequently used for tumors presenting at more advanced stages. The success of CRT treatment is influenced by diverse factors including anatomic location and stage, etiology due to infection with the human papillomavirus (HPV), pathologic features, genomic and epigenetic changes in the tumor, prior therapy, and other factors. As is the case for many solid tumors, the tumor microenvironment is a significant determinant of CRT response, particularly the tumor immune microenvironment (TIME) and the tumor metabolic status.

Supported by the German Cancer Aid (R.K.), the German Research Foundation (KFO262) grant 190230491 (R.K.), and the Foundation Tumor Research Head and Neck (Stiftung Tumorforschung Kopf Hals) (R.K.).

Disclosures: S.L. is an advisory board member for AstraZeneca.
Solid markers to define the tumor microenvironment (TME) according to CRT response are, however, still missing. Tumor oxygenation and functional mitochondria are crucial for successful CRT response.2,6 Mitochondria, as the most important producers of reactive oxygen species (ROS), are the end mediators of CRT-induced cell damage. Apoptosis is initiated via ROS signaling, and ROS also induce damage to mitochondrial DNA. Additionally, ROS are necessary for fixing radiation-induced DNA strand breaks.7–9 The hallmark of radiation resistance, on the other hand, is hypoxia and increased use of glycolysis and production of lactate, even in the presence of oxygen (aerobic glycolysis/Warburg effect) for energy production instead of more effective, mitochondrial oxidative phosphorylation.10,11 Aerobic glycolysis is observed independently of tumor oxygenation and has been shown to follow a compartmentalized spatial distribution in the TME, leading simultaneously to areas with predominantly oxidative phosphorylation and predominantly glycolytic areas, which coexist in a mutual symbiosis.12 Nevertheless, solid tumors in general, and HNSCC in particular, are characterized by an accumulation of lactate contributing to radioresistance by scavenging of ROS.13 Additionally, tumor cell—derived lactate is known to inhibit CD8+ cytotoxic T cells (CTL).14,15 A CTL-dominant tumor immune infiltrate, however, has been shown in many different solid tumors to be predictive of therapy response. In HPV-positive oropharyngeal squamous cell carcinomas (OPSCC), which are known for favorable response to CRT, we have already shown an increased CD8/CD4 ratio as well as a correlation of a CTL-dominant tumor immune infiltrate with a mitochondrial-rich tumor metabolism.16 Therefore, it is hypothesized that a glucose-dependent or mitochondrial-rich tumor metabolism can determine whether immunosuppression or effective antitumor immune response predominates in the TME. It is specifically anticipated that tumors characterized by both a CTL-dominant tumor immune infiltrate and a mitochondrial-rich tumor metabolism would experience the most favorable response to CRT.

To elucidate the interdependencies of tumor metabolism and the TME, and their role in therapy response, immune and metabolic characteristics as well as outcomes of HNSCC treated with primary CRT were correlated in both an institutional cohort and in The Cancer Genome Atlas (TCGA) HNSCC cohort. Additionally, dependency of radiation effects on ROS and metabolic modulation in vitro was examined in a three-dimensional HNSCC spheroid/immune cell co-culture model to determine whether ROS production may link metabolic status to immune response.

Materials and Methods

Patient Data and Tumor Material

A retrospective cohort of 73 HNSCC patients, receiving CRT in definitive indication at the Department of Radiotherapy at the University Hospital Regensburg from 2005 to 2010, was established in cooperation with the Institute of Pathology of the University of Regensburg. Overall survival data were obtained by the cancer registry of the Tumor Center Regensburg. All patients received nonsurgical treatment consisting of cisplatin-based CRT. Patient characteristics and social histories were obtained from medical reports. Representative formalin-fixed, paraffin-embedded tumor tissues were retrieved from the archives of the Institute of Pathology of the University of Regensburg. The study was approved by the institutional review board of the University of Regensburg.

Immunohistochemistry

Immunostaining was performed on 4-μm-thick sections of formalin-fixed, paraffin-embedded specimen after deparaffinization and microwave-based antigen retrieval as previously described.16 The View DAB Detection Kit (Roche, Basel, Switzerland) was used on a Ventana BenchMark platform (Roche) for the following antibodies: CD4 (Clone SP35; Roche), CD8 (Clone SP57; Roche), forhead box P3 (Clone 236A/E7; Thermo Fisher Scientific, Bremen, Germany), and cytochrome c oxidase subunit 5B (COX5B) (Clone 1E8; Sigma-Aldrich, Taufkirchen, Germany). Immunostaining for glucose transporter 1 (GLUT1) (Clone SPM498; LabVision, Fremont, CA) was performed manually with an appropriate horseradish peroxidase—conjugated secondary antibody.

Evaluation of Immunohistochemical Staining

Whole slides were used for analysis of immunohistochemistry. Tumor infiltrating lymphocytes were manually counted within tumor cell nests of four to five representative high power fields and an average number of lymphocytes per high power field was calculated.

The expression levels of COX5B and GLUT1 by tumor cells were semiquantitatively evaluated using the H-score. Here, the percentage of strongly stained cells (3×), the percentage of moderately stained cells (2×), the percentage of weakly stained cells (1×), and the percentage of unstained cells (0×) were added, generating a score between 0 and 300. All immunohistochemical evaluations were performed by an experienced pathologist blinded to patient outcome.

TCGA Database Analysis

TCGA data bank analysis was performed on the CBioPortal for Cancer Genomics website (http://www.cbioportal.org, last accessed August 2016). The Head and Neck Squamous Cell Carcinoma Provisional TCGA cohort with available mRNA data was analyzed for mRNA up- or down-regulation stratified according to mean mRNA expression levels for all tumors (z-score threshold = 0). mRNA and clinical data were downloaded for further SPSS software—based survival analyses (SPSS software version 22.0; IBM SPSS Statistics, Armonk, NY).

Cell Line and Tumor Spheroids

HPV16-positive UM-SCC-47 cells17 were maintained in a combination of Dulbecco’s modified Eagle’s medium, 10% fetal calf serum, and penicillin-streptomycin, 1%.
Spheroids were created by the hanging drop method. Briefly, 20,000 UM-SCC-47 cells were suspended in 20 μL of complete medium and placed on the lid of a 24-well plate. After 4 to 5 days, hanging drops were transferred into agarose-coated wells.

**Radiation and Clonogenic Assay**

Cell irradiation was performed with the RS 2000 Biological X-ray Irradiator (Rad Source, Buford, GA). UM-SCC-47 cells (n = 500 to 1000) were seeded in 6-well plates and exposed to different single radiation doses after sufficient adhesion time (4 to 24 hours). Fourteen days later, colonies were fixed with 10% formalin and stained with hematoxylin for 10 minutes. Colonies (cell aggregations with >50 cells) were counted, and the surviving fraction was calculated by dividing the number of colonies formed by the number of cells plated, multiplied by the plating efficiency.

**Spheroid Immune Cell Co-Cultures**

Peripheral blood mononuclear cells (PBMCs) were collected from fresh heparinized blood of healthy donors and processed immediately. After Ficoll-Hypaque density gradient centrifugation and carboxyfluorescein succinimidyl ester (CFSE)-labeling according to the manufacturer’s instructions (CellTrace CFSE Cell Proliferation Kit, Life Technologies, Gaithersburg, MD), PBMCs were added to spheroids in agarose-coated wells of 24-well plates.

Migration of CFSE-labeled PBMCs toward tumor spheroids was monitored with an inverted microscope by recording immune cell attraction around spheroids at ×10 magnification. The number of fluorescent PBMCs aggregating around one spheroid was determined by ImageJ software version 1.49v (NIH, Bethesda, MD; http://imagej.nih.gov/ij) (Supplemental Figure S1).

**ROS Measurement**

UM-SCC-47 (2.5 × 10^5 to 5 × 10^5) were seeded in a T25 culture flask and incubated for 4 days. ROS production was measured the day after treatment. Cells were trypsinized, and 200 μL of 10 μmol/L 2’,7’-dichlorofluorescin diacetate (CM-H2DCFDA; Molecular Probes, Eugene, OR) containing phosphate-buffered saline with Ca++ and Mg++ was added to each well. After incubation at 37°C for 30 minutes and respective treatment, ROS-producing cells were captured by a fluorescence microscope, and fluorescence intensity was quantified by ImageJ software.

**Statistical Analysis**

Unpaired two-tailed t-test was applied for discrimination of mean CD8/CD4 ratios according to different metabolic tumor phenotypes. Twenty-month and 60-month overall survival rates were calculated by the Kaplan-Meier method and log rank test for statistical significances. Chi-square test was used to compare GLUT1 and mitochondrial superoxide dismutase (SOD2) up- or down-regulation in patient tumors. P < 0.05 was considered statistically significant.

**Results**

**Institutional HNSCC Patient Cohort**

To study the interdependencies of tumor metabolism, TIME, and response to CRT, a retrospective HNSCC cohort consisting of 73 HNSCC patients (oral cavity, oropharynx, hypopharynx, larynx tumors) was established. Patient and tumor features are listed in Table 1, and hazard ratios (HR) for 5-year overall survival are listed in Table 2. Included patients were CRT-naive at the time of the biopsy and had received primary, nonsurgical treatment afterward consisting of cisplatin-based CRT at the Department of Radiotherapy, University Hospital Regensburg, from 2005 to 2010. Average Karnofsky performance score, available for 32 patients, was 80% (ranging from 50% to 100%). Radiation was administered as intensity-modulated radiotherapy (56%) or intensity-modulated arc therapy (37%). The remainder received 3-dimensional radiotherapy (7%). In 51% of cases, radiation was hyperfractionated/accelerated. Average total radiation dose was 69 Gy (SD = ±3.3 Gy). Additionally, all patients received 40 mg/m^2 cisplatin with a mean cumulative dose of 181 mg (SD = ±60 mg). Four patients received additional doses of carboplatin, whereas for four patients, a dosage reduction of 50% to 75% had to be performed. Formalin-fixed, paraffin-embedded tumor tissues of the most recent biopsies before CRT initiation were used for histologic and immunohistochemical evaluations. All patients presented with an advanced stage of disease [90% of patients with Union for International Cancer Control (UICC) stage IV, 10% of patients with UICC stage III]. Lymph node metastases were present in 83% of patients. The best clinical predictor of 5-year survival was T stage with a trend toward improved survival for patients with stage T2 [HR, 0.170; 95 % CI, 0.023–1.248; P = 0.081]. Twelve patients (16.4%) were treated for recurrences after prior surgical resection without CRT. P16 as a surrogate marker for HPV-related HNSCC was positive in seven cases (9.6%) and showed a trend toward improved 5-year survival with a HR of 0.444 (95 % CI, 0.138–1.429; P = 0.173). Patients with oral cavity carcinomas (HR, 1.575; 95 % CI, 0.743–3.338; P = 0.236) and moderately differentiated HNSCC (HR, 1.492; CI, 0.801–2.777; P = 0.207) showed a modest trend toward worse 5-year survival.

**Metabolic and Immunologic Characteristics of the HNSCC Patient Cohort**

All immunohistochemical analyses were performed on whole specimen sections of the most current biopsies before CRT initiation. To characterize the metabolic status, HNSCC were evaluated for COX5B and GLUT1 expression. GLUT1, which facilitates glucose transport across

plasma membranes, serves as an indicator of anaerobic, glucose-dependent, and glycolytic tumor metabolism.18–20

COX5B, which is a subunit of the last enzyme in the mitochondrial electron transport chain, had shown differential expression patterns in a previous study of HPV-positive and -negative oropharyngeal squamous cell carcinomas, and was used as a marker for mitochondrial-rich, aerobic tumor metabolism.16

The mean expression intensity of all 73 cases according to the H-score was 140 (SEM = 19 ± 0.7089) for COX5B and 160 (SEM = 16 ± 0.4573) for GLUT1. HNSCC were further stratified into COX5B low and high tumors, as well as GLUT1 low and high tumors, according to the mean expression levels of all tumors.

To assess the TIME, HNSCC were evaluated for infiltration by CD8+ CTL and CD4+ T helper cells. Average number of CD8+ CTL and CD4+ T helper cells per tumor high power field was 19 (SEM = ±3.638) and 16 (SEM = ±1.861), respectively. As an indicator of antitumor immune response, the CD8/CD4 ratio was calculated, with a mean ratio of 1.4 (SEM = ±0.199). HNSCC were further stratified into CD8/CD4 low and high tumors according to the mean CD8/CD4 ratio of all tumors.

Correlating metabolic with immunologic characteristics, HNSCC with high COX5B expression presented with a trend toward an increased CD8/CD4 ratio (P = 0.0745). Vice versa, tumors with high GLUT1 expression had a significantly decreased CD8/CD4 ratio (P = 0.0260) (Figure 1, A, B, E, and F). Additionally, COX5B high tumors also had a significantly increased number of tumor-infiltrating forhead box P3+ regulatory T cells (Tregs). GLUT1 expression, by contrast, had no impact on infiltration by Tregs (Figure 1, C, D, G, and H).

Predictive and Prognostic Features of Metabolic and Immune Markers and Marker Combinations

Twenty-month overall survival (short-term survival is considered an indicator of initial therapy response) and 60-month overall survival were analyzed by Cox regression (Table 3) and Kaplan-Meier method (Figure 2). Mean survival time was 30.1 months (95% CI, 25.0–35.1). In separate evaluations of immune and metabolic markers, the CD8/CD4 ratio provided the best information on short-term survival, with a trend toward an increased HR (HR, 1.825, 95% CI, 0.793–4.197; P = 0.157) for patients with a decreased CD8/CD4 ratio. Interestingly, patients with low tumor GLUT1 expression presented with

HNSCC, head and neck squamous cell carcinoma; UICC, Union for International Cancer Control.
significantly worse long-term survival (HR, 1.753, 95% CI, 1.010–3.043; P = 0.046).

Because we hypothesized that an active antitumor immune response can only emerge in the presence of a favorable metabolic TME, we analyzed the effect of different immune and metabolic marker combinations on short- and long-term survival. We anticipated that a combination of an aerobic, mitochondrial-rich (high COX5B) or glucose-independent (low GLUT1) tumor metabolism together with a CD8-dominant tumor immune infiltrate (high CD8/CD4 ratio) would represent TMEs predisposing to a strong therapy-related antitumor immune response leading to improved CRT efficacy. Only eight and nine of 73 patients, respectively, had an increased CD8/CD4 ratio together with high COX5B or low GLUT1 expression (Figure 2, A and B). Short-term survival was better in tumors combining high CD8/CD4 together with high COX5B (P = 0.053) or low GLUT1 (P = 0.033) as compared to all other tumors (Figure 2, C and D). Combining the two metabolic markers with CD8/CD4 ratio, a subset of 14 patients may be defined that is characterized by a favorable immune and metabolic TME (high CD8/CD4 and high COX5B or low GLUT1), who demonstrated an excellent outcome with a short-term survival fraction of 85.7% as compared to all other patients with a survival fraction of 45.8% (P = 0.008) (Figure 2, E and F). With regard to long-term survival, a significantly improved
outcome was demonstrated for the subset of patients with a high CD8A/CD4 ratio and low GLUT1 or high COX5B, and an unfavorable signature defined by low CD8A, low COX5B, and high GLUT1. A favorable gene signature was found in 41 patients (7.87%), and an unfavorable gene signature in 132 patients (25.34%). Patients with a favorable immune and metabolic gene signature presented with markedly improved short-term (P = 0.013) and long-term (P = 0.048) survival (Figure 3E).

Because we hypothesized that part of the beneficial outcome of tumors with high CD8A, high COX5B, and low GLUT1 can be attributed to the proapoptotic and immunomodulatory effects of ROS, the levels of SOD2 were next assessed in tumors with favorable and unfavorable immune and metabolic gene signatures. This mitochondrial enzyme catalyzes the conversion of superoxide (O₂⁻) into hydrogen peroxide, which is an important intracellular messenger and involved, among others, in induction of apoptosis and lymphocyte activation.¹¹,¹² The percentage of tumors with SOD2 up-regulation was significantly higher in the favorable immune and metabolic group (46.3%) as compared to the unfavorable group (29.5%; P = 0.0466) (Figure 3F).

Glycolysis Inhibition and Radiation Synergistically Induce Reactive Oxygen Production In Vitro and Induce Chemotaxis of Immune Cells toward UM-SCC-47 Spheroids

An effective CRT response relies on radiation-induced ROS production.¹³,¹⁴ ROS, particularly hydrogen peroxide, are important messengers of tumor cell death and antitumor immune response.¹⁵ Mitochondria are the main source of ROS production. Therefore, the degree of radiation-induced ROS accumulation was hypothesized to depend on the metabolic phenotype...
and radiation on chemotaxis of immune cells toward radiation. Afterward, PBMCs isolated from healthy human donors were fluorescently labeled and added to treated tumor spheroids. Because it was hypothesized that ROS secretion by treated spheroids might play a role in mediating chemotaxis, the optimal time point was determined in preliminary experiments by assessing PBMC migration at 1 hour, 3 hours, 5 hours, 12 hours, and 24 hours. In subsequent experiments, migration of PBMCs toward spheroids was measured after 5 hours with a fluorescence microscope. Although DGL treatment had no effect on PBMC attraction, and 10-Gy radiation slightly increased the number of PBMCs migrating toward tumor spheroids, spheroid growth in the presence of DGL followed by radiation exposure caused a significantly higher chemotaxis of PBMCs to spheroids (Figure 4, C and D). To elucidate the role of DGL and radiation-induced ROS production in PBMC chemotaxis, ROS production was inhibited via the ROS scavenger N-acetylcysteine (NAC). Addition of 10 mmol/L NAC before PBMC spheroid co-cultures completely abrogated the effect of immune cell chemotaxis to below baseline (Figure 4D).

**Discussion**

In this study, the interdependencies of the TIME and tumor metabolism in HNSCC and how these characteristics affect survival in HNSCC patients was assessed. Over the last decades, the tumor immune profile has gained more and more importance as a predictive and prognostic factor in solid tumors, including the recognition of CRT as an inducer of an antitumor immune response. The pre-existing TIME of HNSCC is highly variable and rendered dysfunctional by tumor-associated immunosuppression and immune escape. In this scenario, an unfavorable equilibrium of protumor components, such as myeloid-derived suppressor cells, Tregs, tumor-associated macrophages or eosinophils, and antitumor components such as CD8+ CTL, CD4+ T helper cells, which can have protumor and anti-tumor activities, natural killer cells, and dendritic cells, preclude successful tumor elimination. Correspondingly, the character of the local tumor immune response strongly impacts therapy efficacy and outcome. In particular, a pre-existing CD8+ CTL dominant tumor immune infiltrate has been shown in many different solid tumors to be beneficial for survival and therapy response. Due to the high variability of different tumor infiltrating immune cell subtypes, ratios between T-cell subsets have been shown to provide even better information on patient survival. In this study, the tumor infiltrating CD8/CD4 ratio was used to define tumors with a CD8-dominant antitumor immune infiltrate.

To characterize the tumor metabolism, the expression of two proteins involved in energy metabolism was assessed: GLUT1 and COX5B. GLUT1 is widely accepted as a surrogate marker of glycolytic or glucose-dependent metabolism. Increased GLUT1 expression in HNSCC and esophageal cancers has been associated with more
aggressive growth and poorer survival in several studies.\textsuperscript{20,34} As a marker for a mitochondrial-rich and aerobic tumor metabolism, COX5B, which is a subunit of the cytochrome c oxidase complex, also known as Complex IV, was used. This is the last enzyme in the mitochondrial electron transport chain. We and others have already shown increased expression of COX5B in HNSCC and other epithelial malignancies.\textsuperscript{16,35,36} A glucose-dependent tumor metabolism provides a TIME, which is more capable of secreting accumulated lactate, which results in a logical pH. In a lactate-rich TME, they are therefore not shuttled into the Krebs cycle and respiratory chain. The amount of lactate in the TME of these different metabolic phenotypes is crucial, because it affects patient outcome. For example, solid tumors with high intratumoral lactate levels have been shown to metastasize more frequently and to be associated with a decreased overall survival as compared to tumors with low lactate levels.\textsuperscript{38} Besides stimulating several proangiogenic and migratory factors as transforming growth factor-\(\beta\) and vascular endothelial growth factor, lactate also impacts tumor immune escape and response to CRT. Lactate inhibits cytokine release from dendritic cells and inhibits CD8\textsuperscript{+} CTLs. Activated CD8\textsuperscript{+} CTLs rely on glycolysis for energy production and secretion of lactate into the extracellular space to maintain a physiological pH. In a lactate-rich TME, they are therefore not capable of secreting accumulated lactate, which results in a decrease of intracellular pH and consecutive dysfunction of their cytotoxic activity.\textsuperscript{13} Additionally, lactate levels have been positively correlated with radioresistance in HNSCC.\textsuperscript{15} This may be due to the antioxidant capacities of lactate as a ROS scavenger. ROS, on the other hand, are crucial for their cytotoxic activity.\textsuperscript{13} Lactate levels have also been shown to be associated with a decreased overall survival as compared to tumors with low lactate levels.\textsuperscript{38} Corresponding to the inhibitory effect of lactate on effective chemotherapy or radiation-induced tumor cell DNA damages because they bind and fixate DNA strand breaks.\textsuperscript{39} In the correlative analyses of tumor-infiltrating lymphocytes and metabolic phenotypes in HNSCC, a significant interdependence of tumor metabolism with the TIME was identified. Corresponding to the inhibitory effect of a glycolytic tumor metabolism on the cytotoxic tumor immune response, the CD8/CD4 ratio was significantly lower in tumors with high GLUT1 expression as opposed to tumors with low GLUT1 expression. Mitochondrial-rich tumors with high COX5B expression, on the other hand, were also associated with higher CD8/CD4 ratios, suggesting that an aerobic tumor metabolism provides a TIME, which is more
permissive for a cytotoxic antitumor immune response. Additionally, COX5B was significantly higher in tumors with a strong Treg infiltrate as compared to tumors with only a few Tregs. The metabolism of Tregs is unique in that they use oxygen-dependent fatty acid oxidation for energy production. Therefore, it is assumed that only tumors with an aerobic metabolism provide the necessary oxygen supply to allow Treg infiltration. Regarding the high CD8/CD4 ratio in nonglycolytic and aerobic tumors, we have already observed very similar features of a dominant mitochondrial-rich and CD8/CD4 high TME in HPV-positive OPSCC as compared to HPV-negative ones. Because HPV-positive OPSCC are known for their excellent prognosis and response to CRT, there is a strong suspicion that TMEs featuring these characteristics generally present with an improved response to therapy and better survival.

The tumors of our (predominantly HPV-negative) cohort were therefore stratified according to their metabolic and immunologic TME features and short-term survival (20 months) was assessed, which provides information on CRT response, as well as long-term survival (60 months). Only 11% and 12% of all patients, respectively, showed an immune and metabolic tumor phenotype characterized by a high CD8/CD4 ratio together with a mitochondrial-rich or glucose-independent tumor metabolism. The respective tumors presented with a significantly improved short-term survival. Because the cases of patients with a favorable immune and metabolic tumor phenotype were fairly small in our own cohort, statistical bias due to disproportionate numbers cannot be excluded.

Therefore, mRNA data from the HNSCC collective of the TCGA data bank was used to assess the significance of a

Figure 4  Radiation and inhibition of glycolysis cause reactive oxygen species (ROS)–dependent peripheral blood mononuclear cells (PBMCs) chemotaxis toward head and neck squamous cell carcinoma (HNSCC) spheroids. A and B: 2-Deoxyglucose (DGL) treatment and radiation induce an increase of ROS production in UM-SCC-47 cells. Tumor cells were grown for 4 days in the presence or absence of DGL. After H2DCFDA (ROS probe) labeling, cells were exposed to 10-Gy radiation or mock treatment, and ROS production was measured under a fluorescence microscope (A, representative images) followed by ImageJ software version 1.49v (NIH, Bethesda, MD; http://imagej.nih.gov/ij) quantification of fluorescence intensity (B). C and D: DGL treatment combined with radiation exposure leads to increased PBMC chemotaxis toward UM-SCC-47 spheroids (spheroid borders are depicted in blue). Tumor cells were grown in the presence or absence of DGL for 4 days and transferred into agarose-coated wells. After 10-Gy radiation or mock treatment, spheroids were co-cultured with carboxyfluorescein succinimidyl ester (CFSE)-labeled human PBMC, and PBMC migration was imaged under a fluorescence microscope 5 hours after co-culture initiation. DGL-treated spheroids attracted significantly more PBMCs after radiation exposure than control spheroids (D). Addition of the ROS scavenger N-acetylcysteine (NAC) abrogated this effect, indicating a ROS-related mechanism. All spheroid/PBMC co-culture experiments were performed in triplicates Data are expressed as means ± SEM (B and D). n = 3 (B, experiments). *P < 0.05; **P < 0.01. Scale bar = 400 μm. Original magnification, ×10.
favorable immune and metabolic tumor phenotype in a bigger, independent cohort. In contrast to our own cohort, this collective includes 522 patients of all stages treated with primary surgery with or without CRT. In analogy to the results of our cohort, CD8A expression inversely correlated with GLUT1 expression. Although neither GLUT1 nor COX5B mRNA levels alone can predict survival, patients with increased CD8A presented with a better prognosis. The best information on long-term and short-term survival may be achieved by combining immune and metabolic mRNA expression levels. An improved outcome for patients with a favorable immune and metabolic tumor phenotype (high CD8A, high COX5B, low GLUT1) as compared to an unfavorable phenotype (low CD8A, low COX5B, high GLUT1) was confirmed.

In perspective, we think that our marker combination may constitute a helpful tool to distinguish HNSCC patients who would benefit from a CRT-based treatment approach, instead of a surgical therapy, in particular because there still exist no reliable clinical, histological or immunohistochemical features that can select patients with particularly CRT-sensitive tumors.

Oxidative stress is an important signal transduction mechanism of radiation- and chemio-induced apoptosis, and end effector of radiation damage with significant implications for response to radiotherapy and CRT. Therefore, we hypothesized that ROS, such as super oxide (O₂⁻) or hydrogen peroxide may also constitute important mediators between tumor metabolism and TIME contributing to the good prognosis of tumors with a favorable immune and metabolic TME. A comparison of SOD2 mRNA expression in the TCGA HNSCC cohort subgroups of favorable and unfavorable immune and metabolic patients supports a strong association between up-regulated SOD2 and favorable immune and metabolic tumors; and down-regulated SOD2 and unfavorable immune and metabolic tumors. SOD2 catalyzes the conversion of O₂⁻ to hydrogen peroxide. Hydrogen peroxide is not only necessary for the fixation of DNA strand breaks, but is also involved in the initiation of redox-sensitive signaling cascades such as the MAPK/ERK-pathway. High SOD2 levels have been shown to increase radiosensitivity in vivo.

To investigate the connection of tumor metabolism and immune cells in the context of radiation-induced ROS production, a 3-dimensional spheroid model of UM-SCC-47 cells, which was metabolically modulated via the glucose inhibitor DGL, was used. First, the changes in ROS production via metabolic modulation and radiation were examined. As previously shown, the extended inhibition of glycolysis by DGL for 96 hours or exposure to radiation both caused an increase in ROS production. Additionally, radiation of DGL-treated tumor cells increased ROS production even further. DGL has already been shown to radiosensitize tumor cells in vitro and reduce tumor growth in vivo together with radiation. Several clinical trials of malignant glioma patients also showed an increase in survival for patients treated with DGL and radiation. The effect of DGL- and radiation-treated UM-SCC-47 tumors was consecutively assessed on the chemotaxis of human immune cells. In a tumor spheroid/PBMNC co-culture model, we showed an increased migration of immune cells toward DGL-treated spheroids after radiation exposure. The complete abrogation of the immune cell migration toward the spheroid by the ROS scavenger NAC suggests this effect to be ROS and oxidative stress related. Supporting our observations, it has already been shown that chemokine-induced T-cell trafficking depends on the uptake of hydrogen peroxide by T cells. Another group demonstrated that treatment with an SOD2 mimic leads to radiosensitization and increased macrophage influx in a murine xenograft HNSCC tumor model.

The interaction of tumor metabolism and tumor immune infiltrate is, however, complex and dependent on many different factors. For example, immune checkpoint modulators represent a potential mechanism of metabolism-mediated antitumor immune response. To assess the effect of changes in GLUT1 expression on immune checkpoint molecules, a biological network analysis was performed, which revealed network-wide changes of most key immune checkpoint molecules in response to increased GLUT1 levels. Evaluation of the network identified GLUT1-mediated control of AKT as a mediator of nuclear factor κB signaling resulting in changes in immune checkpoint molecule expression (Supplemental Figure S3). Interestingly, it was just recently shown that aerobic glycolysis and lactate are features of acquired radioresistant cells and that this is an AKT-mediated phenomenon, because radioresistance was reversed by AKT inhibitors. Our initial network studies point toward new targets to further investigate the interactions of tumor metabolism and antitumor immune response.

One weakness of the study is the patient selection of the HNSCC cohort treated by primary CRT. The patients included are generally characterized by progressed tumors and overall bad health status including operability, disease stage, comorbidities, etc. This is reflected in our cohort by a majority of UICC stage IV patients (90.4%) and the remainder of patients with an UICC stage III, as well as an average Karnofsky performance status of 80%. Furthermore, 12% patients were CRT-naïve, but suffered from recurrences, which might behave differently under CRT than primary tumors. In Germany, primary CRT is typically reserved for advanced cases with palliative approaches, as well as for tumors that cannot be resected due to their anatomic location, or for patients whose comorbidities do not allow surgery. Therefore, this cohort is biased toward patients with rather poor prognoses as demonstrated by a mean overall survival of 30.1 months. Hence, multiple factors beyond tumor biology contribute to outcome and probably have a bigger effect on long-term survival than the immune and metabolic tumor status. This most likely explains why the excellent short-term survival of favorable immune and metabolic tumor phenotypes does not result in a superiority regarding long-term survival. Therefore, long-term survival of these advanced tumor patients seems to be determined by other factors than immune and metabolic tumor phenotype. One important parameter in this context is p16 positivity as a surrogate marker for HPV infection in OPSCC. HPV-positive OPSCCs are known for their good radiotherapy response. Additionally, we have shown in a previous study that...
HPV-positivity in OPSCC is associated with high numbers of tumor-infiltrating CD8+ CTL and a glucose-independent, mitochondrial-rich tumor metabolism. In our study, however, p16-positive HNSCC only showed a trend toward better survival, which is probably due to the low number of positive cases.

In summary, our study demonstrates a strong connection between the TIME and tumor metabolism, and points out the relevance of this interdependence for therapy response in HNSCC patients. Mechanistically, our study suggests ROS-dependent signaling as one potential mediator connecting tumor metabolism and the TIME. Together, these findings point toward future strategies for integration of assessment of immune and metabolic marker combinations in the clinical setting to select patients likely to benefit from CRT.
