Epidemiologic studies report improved breast cancer survival in women who receive ketorolac (Toradol) for postoperative pain relief compared with other analgesic agents. Ketorolac is a racemic drug. The S-enantiomer inhibits cyclooxygenases; R-ketorolac is a selective inhibitor of the small GTPases Ras-related C3 botulinum toxin substrate 1 (Rac1) and cell division control protein 42 (Cdc42), which are signaling molecules up-regulated during breast cancer progression and metastasis. The goal of this study was to determine whether R-ketorolac altered breast cancer development in the mouse mammary tumor virus-polyoma middle T-antigen model. Mice were administered ketorolac orally at 1 mg/kg twice daily to approximate the typical human dose. Mammary glands were analyzed for tumor number and immunohistochemical markers of proliferation and differentiation. R-ketorolac treatment significantly reduced mammary epithelial proliferation, based on Ki67 staining, and suppressed tumor development. Proliferative mammary epithelium from R-ketorolac-treated mice displayed greater differentiation, based on significantly higher total E-cadherin and decreased keratin 5 staining than epithelium of placebo-treated mice. No differences were detected in estrogen receptor, progesterone receptor, β-catenin, or vimentin expression between placebo and R-ketorolac treatment groups. These findings indicate that R-ketorolac treatment slows tumor progression in an aggressive model of breast cancer. R-ketorolac may thus represent a novel therapeutic approach for breast cancer prevention or treatment based on its pharmacologic activity as a Rac1 and Cdc42 inhibitor. (Am J Pathol 2018, 188: 515–524; https://doi.org/10.1016/j.ajpath.2017.10.018)

Epidemiologic evidence indicates that women who receive ketorolac (Toradol) for pain relief after breast cancer surgery have improved survival, although the basis for this effect has not been determined.1–5 Ketorolac is a nonsteroidal anti-inflammatory drug that inhibits cyclooxygenase (COX) enzymes, whereas the R-form has little or no COX inhibitory activity.6–9 However, evidence is mounting that R-enantiomers of certain nonsteroidal anti-inflammatory drugs are distinct chemical entities with pharmacologic activities against novel non-COX targets.10–13 We previously reported that the R-enantiomer of ketorolac is an allosteric inhibitor of the Rac1 [Ras homolog (Rho)-family small GTPases Ras-related C3 botulinum toxin substrate 1] and Cdc42 (cell division control protein 42) GTPases.13 R-ketorolac is a robust inhibitor of growth factor or serum activation of Cdc42 and Rac1, with a potency and efficacy similar to the small-molecule Cdc42 and Rac1 inhibitors, CID2950007/ML141 and NSC23766, respectively.13,14

Furthermore, R-ketorolac, but not the S-enantiomer, inhibited Rac1- and Cdc42-dependent downstream signaling, growth factor-stimulated actin cytoskeleton rearrangements, cell adhesion, migration, and invasion in tumor cells.13,14

In many human cancers, aberrant Rho-family signaling because of changes in GTPase expression or activity is a critical contributor to tumor development and progression.15–22 Rac and Cdc42 GTPases regulate cytoskeletal dynamics important in adhesion, migration, and invasion and other cancer-relevant functions such as gene transcription, cell cycle progression, cell survival, and transformation. Several studies have demonstrated increased Rac1 and Cdc42 activity in cancer by mechanisms that include GTPase overexpression, activating mutations, changes in expression or activity of proteins that control Rho-family GTPase activation, or changes in activity of GTPase effector molecules.15,23–27 Furthermore, Rac1 and Cdc42 knockdown or inhibition have been reported to decrease breast cancer cell growth, migration, and invasion; enhance sensitivity to ionizing radiation; and restore sensitivity to therapeutic agents such as trastuzumab and tamoxifen.28–36 These findings suggest that Rac1 and Cdc42 may be promising targets for clinical intervention in breast cancer.37

Given the evidence that activated Rac1 and Cdc42 are negative prognostic indicators in breast cancer and that ketorolac treatment may prolong survival after surgery for breast cancer, therapeutic targeting of these proteins by R-ketorolac may lead to a novel approach for breast cancer treatment. To test this hypothesis, we examined the effects of the dual Rac1 and Cdc42 inhibitor R-ketorolac on tumor progression with the use of the mouse mammary tumor virus-polyoma middle T-antigen (MMTV-PyMT) model of breast cancer.38 This genetically engineered model was selected because of its reported similarities to human disease.38 With the use of this model, we demonstrated that chronic treatment with R-ketorolac reduced proliferation of mammary epithelium, delayed mammary tumor development, and slowed mammary lesion progression.

Materials and Methods

Oral Dosage Preparation

Racemic ketorolac-tris salt was purchased from Sigma-Aldrich (St. Louis, MO), and individual R-enantiomer was purchased from Toronto Research Chemicals (Toronto, ON, Canada). As an alternative to gavage for oral delivery, the drug was administered in pills formed from ketorolac powder mixed into transgenic dough (BioServ, Flemington, NJ).39 Ketorolac, as racemic compound or individual enantiomer, was stable for at least 3 months as determined by high-performance liquid chromatography.

Animal Model

FVB/N-Tg(MMTV-PyVT)634Mul/J mice, hereafter referred to as MMTV-PyMT mice, were originally obtained from The Jackson Laboratory (Bar Harbor, ME). The colony was maintained by the University of New Mexico Comprehensive Cancer Center Small Animal Models and Imaging Shared Resource and housed at the Animal Research Facility at the University of New Mexico Health Sciences Center. Mice were maintained at a controlled temperature of 22°C to 23°C, with a 12-hour light/12-hour dark cycle. Water and standard mouse chow were available ad libitum. All procedures were approved by the University of New Mexico Institutional Animal Care and Use Committee and performed in accordance with the NIH’s Guide for the Care and Use of Laboratory Animals.40

MMTV-PyMT female transgenic mice 5 to 6 weeks of age were placed into groups of two to three mice per cage and acclimated to pills by offering placebo pills twice a day for 3 days. Consumption was confirmed by direct observation. Once treatment began, mice received one pill that contained 1.0 mg/kg body weight of drug or placebo twice daily for the 3-week study or twice daily 5 days per week for the 7-week study.

Tissue Analysis

Mammary tissue whole mounts were prepared from fourth abdominal mammary glands in the 3-week study. Resected mammary glands were fixed in 4% paraformaldehyde, followed by two changes of acetone over 8 to 24 hours, then placed in water for 1 hour. After overnight staining in carmine alum (0.2% carmine dye, 0.5% aluminum potassium sulfate), tissues were destained.

For histologic examination and immunohistochemistry of mammary tissue from the 7-week study, the fourth abdominal mammary glands were resected, fixed in neutral buffered formalin, embedded in paraffin, and sectioned longitudinally at 5 to 6 μm for routine hematoxylin and eosin (H&E) staining and immunohistochemistry. For all immunohistochemical staining, sections were rehydrated, endogenous peroxidase activity was blocked with 3% H2O2 in water, and antigen retrieval was performed with 10 mmol/L citrate buffer, pH 6.0, in a microwave oven. Nonspecific antibody binding was blocked with Biocare Medical Blocking Reagent (Concord, PA). Immunohistochemistry was performed with the following primary antibodies: anti-keratin 5 (PRB-160P; Covance, Princeton, NJ) rabbit polyclonal diluted 1:500 for 1 hour; anti-vimentin rabbit monoclonal antibody (ab92547; Abcam, Cambridge, MA) diluted 1:500 for 2 hours. All incubations were performed at room temperature. Secondary reagents included Envision⁺ labeled polymer, anti-rabbit-horseradish peroxidase (HRP; Dako, Santa Clara, CA) applied for 30 minutes at room temperature for...
rabbit antibodies and streptavidin-HRP (Biocare Medical) applied for 30 minutes at room temperature for mouse antibodies. Reactivity was detected using diaminobenzidine (Dako).

Tumor Scoring and Morphometry

Carmine-stained mammary gland whole mounts were imaged with MoticCam 2300 running Motic Images Plus software version 2.0 (Hong Kong, China) on an Olympus (Tokyo, Japan) SZH dissection microscope. Pixel intensity of tumor and non-tumor areas was determined with ImageJ software version 1.47 (NIH, Bethesda, MD; https://imagej.nih.gov/ij/). H&E and immunohistochemistry slides were scanned by an Aperio CS2 scanner (Leica Biosystems, Buffalo Grove, IL), and morphometry was performed with the HALO image analysis platform (Indica Labs, Albuquerque, NM). Tumors were identified on H&E-stained slides as discrete masses >3 mm² that had uniform structure and immunohistochemical staining characteristics and that compressed or infiltrated surrounding parenchyma. Tumor areas were determined using the manual selection tool to outline the tumors. In addition, total epithelial area in each mammary gland was determined on H&E-stained slides by training the HALO Classifier algorithm to distinguish mammary epithelium, both hyperplastic and neoplastic, from stroma. This classifier was then applied to the entire mammary gland section. For quantification of each immunohistochemical stain, the Classifier algorithm was trained to distinguish epithelium from nonepithelial tissue; the epithelium was then analyzed with the appropriate Analysis algorithm modified as necessary for each stain.

RNA Isolation and qPCR

Samples of tumor tissue (30 mg) were frozen in liquid nitrogen and disrupted in buffer provided in an RNeasy Mini Kit (Qiagen, Valencia, CA), using an electric hand drill fitted with nuclease-free 1.5-mL pestles (Kimble-Chase, Vineland, NJ). The tissue lysate was homogenized with the QIAshredder (Qiagen), and RNA was isolated with the RNeasy Mini Kit according to the manufacturer’s protocols. RNA was converted into cDNA with the use of a High Capacity cDNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA) and a TC-3000X Thermocycler (Techne Inc., Burlington, NJ). cDNA was generated from 1000 ng of RNA of each sample. The resulting cDNA (Techne Inc., Burlington, NJ). cDNA was generated from analyzing the treated samples in reference to placebo samples.

Real-time quantitative PCR (qPCR) was conducted with the use of six mouse primers: Rac1, Rac1b, RhoA, Cdc42, PyMT, and β-80 actin (Qiagen; excluding PyMT; catalog numbers QTO1070146, QTO00127673, QTO0197568, QTO0091560, QTO00095242, respectively). PyMT primers used were PyMT forward (5′-CCGGCAGCGCGAGAACTGAGGAGGAG-3′) and reverse (5′-TCAGAGAAGACTCCGGACTCTTA-3′). Fast SYBR Green Master Mix (Applied Biosystems) was used to make a 1:5 master mix for each primer. Samples were loaded in triplicate in 384-well plates with 6 μL of master mix and 4 μL of sample per well. A nuclease-free water sample was used as a negative control, and β-actin was included as a positive control. Genes were amplified on a 7900 HT Fast Real-Time PCR System (Applied Biosystems). Relative expression was calculated with the ΔΔct method, using β-actin for normalizing and analyzing the treated samples in reference to placebo samples.

Protein Isolation and Western Blot Procedures

Proteins were extracted with frozen tumor tissues with the use of protocols modified from Zakharchenko et al. Briefly, 10 to 20 mg of frozen tissue was homogenized in 250 μL of RIPA buffer (50 mmol/L Tris-HCl pH 7.5, 105 mmol/L NaCl, 1% NP-40, 1% sodium deoxycholate, 0.1% SDS, and 2 mmol/L EDTA) with protease inhibitors (catalog number 78439; Thermo Fisher Scientific, Waltham, MA) and phosphatase inhibitors (catalog number 78445; Thermo Fisher Scientific) with the use of an electric drill with a plastic pellet pestle (catalog number 7495150000; Kimble-Chase) attached. Homogenized lysates were incubated on ice for 30 minutes, mixed with a vortex mixer, and briefly sonicated. Lysates were incubated for 30 additional minutes and spun at 16,500 × g for 20 minutes at 4°C to remove debris, and the supernatant was divided into aliquots into a new tube. Protein concentrations were measured with a Pierce BCA Protein Assay Kit (catalog number 23227; Thermo Fisher Scientific).

Proteins (20 μg) were resolved by polyacrylamide gel electrophoresis and transferred to nitrocellulose membrane. Membranes were blocked in 5% milk for 1 hour at 4°C, then blotted with the following antibodies and conditions. GAPase Western blot analyses used anti-Rac1 mouse monoclonal antibody ARCO3, anti-Cdc42 mouse monoclonal antibody ACD03, anti-RhoA mouse monoclonal antibody ARH04 (Cytoskeleton, Inc., Denver, CO) at 1:5000 dilution in 0.1% milk in TBST (13 mmol/L Tris-HCl, 150 mmol/L NaCl, 0.05% Tween-20 at pH 7.4), RhoA antibody was diluted in TBST only. The following rabbit polyclonal antibodies from Cell Signaling (Danvers, MA) were used at 1:1000 dilution: phospho (p)-P12 (RAC1) activated kinase (PAK)1 (Ser144)/PAK2 (Ser141) antibody number 4051, Akt antibody number 9102, Akt antibody number 9272, and mouse monoclonal p-Akt (Ser473) antibody number 4051. All p-PAK, PAK, p-Erk, Erk, and Akt antibodies were diluted in 5% bovine serum albumin in TBST, whereas p-Erk2 was diluted in 5% milk in TBST. Secondary antibody Anti-Rabbit IgG (H+L) HRP Conjugate W401B and Anti-Mouse IgG (H+L) HRP Conjugate W402B (Promega, Madison, WI) were used at 1:5000 dilution in 1% milk in TBST. Blots were stripped at 50°C in stripping buffer (62.5

R-Ketorolac Delays Mouse Mammary Tumors

The American Journal of Pathology  n  ajp.amjpathol.org  517
mmol/L Tris-HCl pH 6.7, 100 mmol/L β-mercaptoethanol, 2% SDS) for 30 minutes, followed by thorough rinsing with MilliQ water and three 10-minute washes in TBST. Blots were reprobed with Vinculin XP rabbit monoclonal antibody (HRP conjugate) number 18799 from Cell Signaling at a 1:1000 dilution in 5% bovine serum albumin in TBST. Vinculin was selected because it did not change as a consequence of Rac1 overexpression in SKOV3ip cells. Western blot images were acquired on ProteinSimple FluorChem R system and analyzed with AlphaView SA software version 3.4.0.0 (ProteinSimple, San Jose, CA). Values for specific proteins were normalized to the vinculin loading control or total protein based on image analysis of Ponceau-stained membrane.\textsuperscript{43} Analysis was completed in Prism software version 6 (GraphPad Software, Inc., La Jolla, CA) with the use of unpaired t-tests that assumed Gaussians distributions with two-tailed \( P \) values at 95% confidence intervals. To confirm no difference in variances between treatments the F test was used.

**Results**

**R-Ketorolac Reduces Epithelial Content of Mammary Glands**

To test the impact of R-ketorolac on mammary epithelial proliferation, 5- to 6-week-old MMTV-PyMT female mice were treated with twice daily oral doses of 1.0 mg/kg R-ketorolac or placebo for 3 weeks. This dosing regimen achieved serum concentrations comparable with those in humans.\textsuperscript{8,9} No significant difference was found between the two treatment groups in palpable mammary nodules or body weight at sacrifice (Supplemental Figure S1). To evaluate epithelial content of the mammary glands, left and right fourth abdominal mammary glands were removed, stained with carmine alum, imaged as whole mounts, and analyzed separately. The results of the analysis were averaged for the histogram. Representative whole-mount mammary gland images for placebo versus R-ketorolac treatment groups are shown in Figure 1, A and B. Quantification of pixel intensity demonstrated a significant reduction in Carmine-stained epithelium in the R-ketorolac treatment group compared with the placebo group (Figure 1C). This indicated reduced epithelial volume in R-ketorolac–treated mice.

From evidence presented in Figure 1, the effects of R-ketorolac treatment were then examined on epithelial proliferation in mice with somewhat more advanced lesions. Mice received 1.0 mg/kg R-ketorolac or placebo twice daily 5 days per week for 7 weeks. No significant difference was found between placebo and R-ketorolac treatment groups in weight gain over the course of the study or in total mammary gland weight at sacrifice (Supplemental Figure S2). As determined by morphometric analysis of mammary gland sections, total epithelial area (hyperplastic and neoplastic) was significantly greater in placebo-treated mice (57.96 ± 19.13 mm\(^2\)) than in R-ketorolac–treated mice (43.37 ± 8.58 mm\(^2\)) (Figure 2, A and B). Moreover, the percentage of the mammary gland area occupied by epithelium was significantly higher in placebo-treated mice (26.8% ± 5.6% versus 21.6% ± 6.5%) (Figure 2B). These findings were in agreement with the first experiment in which reduced mammary epithelium was found in mice treated with R-ketorolac for 3 weeks (Figure 1). A significant difference was found between placebo mice (30.8% ± 8.8% positive nuclei) and R-ketorolac–treated mice (21.9% ± 11.1% positive nuclei) in Ki67 staining.
Three-week treatment with R-ketorolac reduces epithelial area. A and B: Carmine staining of mammary gland whole mounts obtained from mice after 3-week dosing with placebo (A) or R-ketorolac (B). Image analysis was performed on left and right fourth mammary glands; the values were averaged for each mouse with nine mice per treatment group. Darker pixels represent epithelial tissue, whereas lighter pixels represent more fatty tissue. C: Pixel intensity throughout the glands was measured with ImageJ version 1.47 software (NIH, Bethesda, MD; https://imagej.nih.gov/ij). Placebo-treated mice had significantly greater density of staining in the mammary glands than mice treated with R-ketorolac. ****p < 0.0001. Significance was determined with the t-test.

(Figure 2, C and D), but no significant change in nuclear cyclin D1 staining between the groups (Supplemental Figure S3). These findings indicated that R-ketorolac treatment reduced epithelial proliferation.

R-Ketorolac Slows Tumor Development

The mammary glands of mice in the 7-week study contained a complex admixture of epithelial lesions, including hyperplasia, adenomas, and carcinomas, as well as intermediate lesions; there were few advanced carcinomas. This made identification and classification of individual tumors difficult. Thus, stringent criteria were applied to reproducibly distinguish tumors from surrounding lesions (see Materials and Methods). Results showed that significantly fewer R-ketorolac–treated mice had tumors than placebo-treated mice (Figure 3A). Although 100% of placebo-treated mice had one or more discrete mammary tumors, only 50% of R-ketorolac–treated mice had similar tumors. The mean number of tumors per mouse, when all mice were considered, was significantly lower in R-ketorolac–treated mice (0.90 ± 0.99 tumors per mouse) than in placebo-treated control mice (1.73 ± 0.79 tumors per mouse) (Figure 3B). However, when only mice with tumors were considered, no significant difference was found between R-ketorolac–treated and placebo-treated mice in number of tumors per mouse, average tumor size, or total tumor area per mouse (Supplemental Figure S4). These findings suggested that R-ketorolac decreased mammary tumor development in MMTV-PyMT mice based on number of mice developing tumors but did not reduce tumor size or area once tumors were present.

R-Ketorolac Does Not Alter GTPase or PyMT Transcript Expression but Decreases GTPase Protein Levels

Expression of the PyMT transcript, as measured by qPCR, was not altered in the mammary glands of R-ketorolac–treated mice (Supplemental Figure S5). This indicated that reduced expression of PyMT in the mammary glands of R-ketorolac–treated mice was not responsible for decreased tumor development. Similarly, R-ketorolac did not alter transcripts of the Rho-family GTPases, Rac1, a constitutively active variant Rac1b, Cdc42, or RhoA in the mammary glands of ketorolac-treated mice (Supplemental Figure S5). In contrast to the mRNA findings, a significant decrease in Rac1 protein levels and trend toward decrease in Cdc42 protein levels in tumors from R-ketorolac–treated mice compared with placebo control mice was detected (Supplemental Figure S6A). A trend was found toward a corresponding decrease in Rac1 activity (Supplemental Figure S6B). The decrease in the R-ketorolac target GTPases Rac1 and Cdc42 was selective with neither a decrease in the related family member RhoA (Supplemental Figure S6A) nor in total ERK or AKT proteins (Supplemental Figure S7). R-ketorolac decreased AKT signaling as detected by decreased phosphorylated AKT that may account, in part, for the observed reduction in epithelial proliferation in R-ketorolac–treated mice. Rac1 degradation has been reported43–45 and highlighted the complexity of mechanisms that regulate Rac1.

R-Ketorolac Treatment Delays Lesion Progression

The MMTV-PyMT mouse model of breast cancer displays many hallmarks of human breast cancer development and progression,38 including that progression associated with epithelial-to-mesenchymal transition (EMT). To determine the effect of R-ketorolac on lesion progression, immuno-histochemistry and morphometry were used to measure expression of select EMT markers in proliferative mammary epithelium from MMTV-PyMT mice on the 7-week study. Staining for the epithelial marker E-cadherin was almost entirely restricted to cell margins. This staining was quantified as the number of positive pixels per squared millimeter.
of mammary epithelium (Figure 4, A and B). Significant maintenance of staining for E-cadherin was found in the mammary glands of mice treated with R-ketorolac (2.83 ± 0.67 × 10⁵ positive pixels/mm²) compared with placebo (2.33 ± 0.35 × 10⁵ positive pixels/mm²). However, no difference was found between treatment groups in staining for the progression markers β-catenin and cytoplasmic vimentin (Supplemental Figure S8).
R-ketorolac slows mammary tumor development. A: Fourth mammary glands from mice treated with placebo or R-ketorolac were analyzed to distinguish tumors from other epithelial lesions as described in Materials and Methods. Fewer mice receiving R-ketorolac for 7 weeks developed tumors compared with placebo-treated mice. B: The number of tumors per mouse was determined as in A. All mice, including those with and without tumors, were represented in this analysis. Treatment with R-ketorolac reduces the number of tumors per mouse. *P < 0.05. Significance was determined by Fischer’s exact test.

The MMTV-PyMT model is generally considered to represent a luminal type of mammary cancer, and mammary epithelial cells in this model predominantly express keratin 8. However, when polyoma middle T antigen or ErbB2 signaling is activated in these cells, more keratin 5-positive cells appear, indicating a more basal phenotype.46 Increased expression of keratin 5 in human breast tumors is associated with poorer prognosis and enhanced resistance to therapy.47,48 Because of the large size and irregular contour of keratin 5-positive cells in MMTV-PyMT mice, the number of keratin 5-positive cells was estimated by measuring keratin 5 staining per squared millimeter of mammary epithelium. In R-ketorolac–treated mice significantly less keratin 5 staining was found than in placebo-treated mice (3.13 ± 0.029 × 104 versus 3.60 ± 0.42 × 104 positive pixels/mm² epithelium) (Figure 4, C and D), indicative of a less basal phenotype.

Advanced tumors in MMTV-PyMT mice contain fewer estrogen receptor-α–positive (ER+) and progesterone receptor positive (PR+) cells than less advanced lesions.38 Because of the relatively early stage of the lesions in our study, the number of epithelial cells with ER+ and PR+ nuclei was determined in the entire mammary gland, rather than in individual tumors. R-ketorolac treatment did not alter the total number of ER+ or PR+ cells in the mammary epithelium compared with placebo treatment (Supplemental Figure S9). Although there were more tumors in placebo-treated mice than in R-ketorolac–treated mice, this difference was not reflected in an overall loss of ER or PR expression. This was consistent with the observation that few advanced carcinomas were present either in placebo-treated or R-ketorolac–treated mice.

Taken together, these findings indicated that R-ketorolac decreased selected aspects of lesion progression in the MMTV-PyMT model of human breast cancer. Although R-ketorolac treatment resulted in E-cadherin retention, presumably representing decreased EMT, it did not alter expression of the other EMT markers β-catenin and vimentin. Furthermore, reduced numbers of keratin 5-positive cells in the mammary glands of R-ketorolac–treated mice suggested reduced metastatic potential and decreased likelihood of treatment resistance.

Discussion

The Rho-family GTPases Rac1 and Cdc42 are key regulators of the actin cytoskeleton reorganization necessary for normal cell adhesion and migration, and are signaling molecules that modulate broad aspects of cancer cell function.15–22 Our previous studies identified R-ketorolac as a dual Rac1 and Cdc42 inhibitor with the use of a combination of high-throughput screening and computational simulation.17 R-ketorolac is one enantiomer of a racemic drug (Toradol) approved by the Food and Drug Administration for pain relief. Because epidemiologic studies indicate survival advantage for breast cancer patients who received racemic ketorolac postoperatively,1–3 the potential benefits of the R-enantiomer alone were assessed on the development and progression of early mammary gland lesions in the MMTV-PyMT mouse model of breast cancer that recapitulates many key features of human disease.38

The impact of Rac1 and Cdc42 activity on breast cancer development has not been previously studied in the MMTV-PyMT model, but there are similarities between our findings and results reported in other in vivo studies that used genetic or xenograft models. Inhibition of Rac1 by the inhibitor EH0p-016 in a xenograft model that used MDA-MB-435 mammary tumor cells decreased tumor growth and angiogenesis.49 Knockdown of Cdc42 modestly decreased growth of MDA-MB-231 cells in vivo, and pretreatment of tumor cells with the Cdc42 selective inhibitor ML141 decreased the number of mice that developed tumors.35 Genetic ablation of T-cell lymphoma invasion and metastasis 1, a Rac1-activating guanine nucleotide exchange factor, delayed tumor development, decreased the number of tumors per mouse, and led to an increase in tumor-free mice in an MMTV-c-neu breast cancer model.50 Similarly, knockout of dedicator of cytokinesis 1, another Rac1 guanine nucleotide exchange factor, in a breast cancer model that depended on human epidermal growth factor receptor 2

The American Journal of Pathology  ■  ajp.amjpathol.org
decreased mammary intraepithelial lesions and decreased Ki67⁺ tumor cells by approximately 30%. These two studies of genetic disruption of the Rac1 signaling pathway in breast cancer models driven by human epidermal growth factor receptor 2 are consistent with the outcomes of pharmacologic inhibition by R-ketorolac that were observed in MMTV-PYMT mice shown here.

The present study provides additional insights into the potential value of Rac1 and Cdc42 inhibition by R-ketorolac in breast cancer prevention or treatment. Decreased tumor development in R-ketorolac–treated mice was accompanied by retention of epithelial characteristics as determined by the persistence of E-cadherin expression, and reduced basal cell characteristics, as indicated by decreased keratin 5-expressing cells. In studies of MMTV-PyMT tumor organoids, cells with a basal phenotype were shown to be invasive. In the present study, R-ketorolac treatment is likely to contribute to reduced invasiveness by reducing the number of keratin 5-positive cells with a basal phenotype. In the MMTV-PyMT model, reduced E-cadherin and β-catenin expression and de novo expression of vimentin in mammary tumor cells are associated with EMT and increased tumor invasiveness and metastasis. Of interest, loss of E-cadherin in MMTV-PyMT mammary epithelium during mammary carcinogenesis appears to be Rac1 dependent. Loss of E-cadherin is generally the earliest sign of EMT; thus, it is possible that similar staining for β-catenin and vimentin in R-ketorolac– and placebo-treated mice reflected the relatively early stage of mammary lesion development in these samples. Taken together, our observations indicate that ketorolac treatment reduced the progression and invasive potential of mammary gland lesions.

Figure 4  R-ketorolac delays mammary lesion progression. A: Representative images for E-cadherin immunostaining (upper panels) and corresponding morphometric analysis (lower panels) used to quantify E-cadherin staining. B: Quantification of E-cadherin staining from the fourth mammary gland from each mouse treated with placebo or R-ketorolac. Significantly higher E-cadherin staining, indicating reduced epithelial-to-mesenchymal transition, was found in R-ketorolac–treated mice. C: Representative images for keratin 5 immunostaining (upper panels) and corresponding morphometric analysis (lower panels) used to quantify cytokeratin 5. D: Quantification of cytokeratin 5 staining from the fourth mammary gland from each mouse treated with placebo or R-ketorolac. Significantly less keratin 5 staining, suggesting slowed lesion progression, was found in ketorolac-treated mice. Results are shown as the total positive pixel area (µm²) per total epithelial area (mm²). *P < 0.05, **P < 0.01. Significance was determined with the one-tailed t-test. Scale bars = 100 µm. IHC, immunohistochemistry.
and motivates future studies in other models to further delineate the effects and benefits of Rac1 and Cdc42 inhibition on breast cancer development and progression.

The present and earlier studies on the antitumor effects of Rac1 and/or Cdc42 inhibition support further investigations of R-ketorolac as a novel therapeutic approach in breast cancer. Indeed, there are active efforts to identify Rac1 and Cdc42 inhibitors, but the agents identified thus far have not been translated to human use. Retropective studies demonstrated breast and ovarian cancer survival benefit in patients who received racemic ketorolac for indication of pain management as approved by the Food and Drug Administration, but toxicity risks associated with COX inhibition by the S-enantiomer limit racemic ketorolac use to 5 days. The limits are due to the gastrointestinal and cardiovascular side effects and to renal toxicity that are generally attributed to the potent COX inhibitory activities of S-ketorolac (Toradol Oral ketorolac tromethamine tablets; F. Hoffmann-LaRoche, Basel, Switzerland). The lack of COX inhibition by R-ketorolac and the demonstrated inhibition of Rac1 and Cdc42 by racemic ketorolac in humans suggest that R-ketorolac may offer a tractable option for targeting Rac1 and Cdc42 in human disease through rapid repurposing and testing in clinical prevention or treatment trials.
