Inhibition of Cyclooxygenase-2 Suppresses the Recruitment of Endothelial Progenitor Cells in the Microvasculature of Endometriotic Lesions

The incorporation of endothelial progenitor cells (EPCs) into newly developing blood vessels contributes to the vascularization of endometriotic lesions. We analyzed whether cyclooxygenase (COX)-2 signaling regulates this vasculogenic process. Endometriotic lesions were surgically induced in irradiated FVB/N mice, which were reconstituted with bone marrow from FVB/N-TgN [Tie2/green fluorescent protein (GFP)] 287 Sato mice. The animals received β-estradiol 17-valerate once a week and were treated daily with the selective COX-2 inhibitor parecoxib (25 mg/kg) or vehicle (control) for 7 and 28 days. Analyses involved the determination of lesion growth, cyst formation, homing of GFP⁺/Tie2⁺ EPCs, numbers of circulating EPCs, vascularization, cell proliferation, apoptosis, and immune cell infiltration by means of high-resolution ultrasonography, caliper measurements, flow cytometry, histologic analysis, and immunohistochemical analysis. In parecoxib-treated mice, blood circulating EPCs were higher, but numbers of recruited EPCs in endometriotic lesions were significantly lower when compared with controls. This finding was associated with an impaired early vascularization and stromal tissue growth as well as reduced glandular secretory activity of the lesions. Parecoxib-treated lesions further contained less proliferating and more apoptotic cells and exhibited lower numbers of infiltrating macrophages and neutrophilic granulocytes. These findings demonstrate that the inhibition of COX-2 suppresses vasculogenesis in endometriotic lesions, which may contribute to an impaired lesion vascularization and growth. (Am J Pathol 2018, 188: 450–460; https://doi.org/10.1016/j.ajpath.2017.10.013)

Endometriosis is a painful gynecologic disease, which is characterized by the presence of endometriotic lesions in the peritoneal cavity. The survival, proliferation, and spread of the endometrial-like tissue within these lesions are dependent on sufficient vascularization. Accordingly, dense microvascular networks are a typical feature of developing endometriotic lesions. Moreover, endometriosis is associated with the up-regulation of multiple proangiogenic factors and cytokines that can be detected in high concentrations in the peritoneal fluid of patients with endometriosis. Hence, targeting the microvasculature of endometriotic lesions is increasingly suggested as a novel therapeutic strategy in the treatment of the disease. Blood vessel formation in endometriotic lesions involves different cellular mechanisms. Driven by the hypoxia-induced release of angiogenic growth factors, vascular sprouts from vessels of the surrounding tissue progressively grow into the engrafting lesions, where they interconnect with each other and finally form blood-perfused microvascular networks. Besides this angiogenic process, circulating endothelial progenitor cells (EPCs) from the bone marrow contribute to the lesions’ vascularization by incorporation into the endothelial lining of newly developing microvessels, also referred to as vasculogenesis. Angiogenesis and vasculogenesis in endometriotic lesions are dependent on estrogen stimulation. However, although various mechanisms that mediate angiogenesis in endometriosis have already been identified, the regulation of vasculogenesis in endometriotic lesions remains largely unknown.

Cyclooxygenase (COX)-2, the rate-limiting enzyme of the prostaglandin (PG) synthesis pathway, determines the

Supported by Deutsche Forschungsgemeinschaft (German Research Foundation) grant LA 2682/3-1 (M.W.L.).

proliferative activity and viability of EPCs and, thus, represents a potential target for the inhibition of tumor vasculogenesis. Of interest, COX-2 is also highly expressed in endometriosis, and the application of selective COX-2 inhibitors has been suggested as an option for the management of endometriosis-associated pain. Experimental studies further indicate that the inhibition of COX-2 reduces the vascularization of endometriotic lesions. This reduction is partly caused by the suppression of vascular endothelial growth factor (VEGF)-mediated angiogenesis. On the other hand, it may be speculated that targeting COX-2 signaling also affects vasculogenesis in endometriosis.

To test this hypothesis, we surgically induced endometriotic lesions in a previously established murine green fluorescent protein (GFP)⁺/GFP⁻ crossover design model. This model allowed the quantitative assessment of GFP⁺/Tie2⁺ endothelial progenitor cells in the microvasculature of GFP⁻ endometriotic lesions. To generate GFP⁺/Tie2⁺ chimeras, 37 FVB/N mice were lethally irradiated by exposure to a single dose of 8.5 Gy (Figure 1A). After 4 hours, they received the bone marrow of 19 FVB/N-TgN (Tie2/GFP) 287 Sato mice. For this purpose, the donor mice were sacrificed, and the femurs and tibias were flushed with cold phosphate-buffered saline. Subsequently, 2 × 10⁷ bone marrow cells resuspended in 300 μL of cold phosphate-buffered saline were injected via the tail vein into the recipient animals, which were allowed to recover for 4 to 6 weeks for the reconstitution of their bone marrow (Figure 1, B and C).

Materials and Methods

Animals

Twelve- to 16-week-old female FVB/N mice (Institute for Clinical & Experimental Surgery, Homburg/Saar, Germany) and transgenic FVB/N-TgN (Tie2/GFP) 287 Sato mice (Jackson Laboratories, Bar Harbor, ME) with a body weight of 20 to 25 g were used. The animals were housed in open cages (n = 4 to 5 per cage) under a 12-hour day/night cycle and had access to water and standard pellet food ad libitum (Altromin, Lage, Germany).

All experiments were performed according to the German legislation on protection of animals and the NIH’s Guide for the Care and Use of Laboratory Animals and were approved by the local governmental animal care committee (Landesamt für Verbraucherschutz, Saarland, Germany; permission number: 25/2012).

Bone Marrow Transplantation

To generate GFP⁺/Tie2⁺ chimeras, 37 FVB/N mice were lethally irradiated by exposure to a single dose of 8.5 Gy (Figure 1A). After 4 hours, they received the bone marrow of 19 FVB/N-TgN (Tie2/GFP) 287 Sato mice. For this purpose, the donor mice were sacrificed, and the femurs and tibias were flushed with cold phosphate-buffered saline. Subsequently, 2 × 10⁷ bone marrow cells resuspended in 300 μL of cold phosphate-buffered saline were injected via the tail vein into the recipient animals, which were allowed to recover for 4 to 6 weeks for the reconstitution of their bone marrow (Figure 1, B and C).

Induction of Endometriotic Lesions

Peritoneal endometriotic lesions were surgically induced by suturing uterine tissue samples from 19 FVB/N donor mice to the abdominal wall of GFP⁺/Tie2⁺ chimeras, as described previously. Before the induction of endometriotic lesions, estrus cycling of the donor mice was determined to exclude morphologic and functional differences among individual uterine tissue samples attributable to different sex hormone levels. Cytologic analysis of vaginal lavage samples was performed by pipetting 15 μL of 0.9% saline into the vagina. The cell suspension was then transferred onto a glass slide and
examined under a phase contrast microscope (CH-2; Olympus, Hamburg, Germany) to identify animals in the stage of estrus as tissue donors for the experiments.

For harvesting of uterine tissue samples, the donor mice were anesthetized by an i.p. injection of 75 mg/kg of ketamine (Pharmacia GmbH, Erlangen, Germany) and 15 mg/kg of xylazin (Bayer, Leverkusen, Germany). The two uterine horns were excised after midline laparotomy and placed into a Petri dish that contained Dulbecco’s modified Eagle medium (10% fetal calf serum, 100 U/mL of penicillin, 0.1 mg/mL of streptomycin; PAA, Cölbe, Germany). Then, 2-mm tissue samples were removed from the longitudinally opened uterine horns by means of a dermal biopsy punch (Stiefel Laboratorium GmbH, Offenbach am Main, Germany) and microsurgical instruments (Figure 1D).

After laparotomizing the anesthetized GFP+/Tie2+ recipient animals, one tissue sample was fixed with a 6-0 Prolene suture (Ethicon Products, Norderstedt, Germany) to the right and the left site of the abdominal wall (Figure 1E). Subsequently, the laparotomy was closed with running 6-0 Prolene muscle and skin sutures. During the rest of the experiments, physiologic estrogen levels in the irradiated mice were achieved by s.c. injection of 100 mg/kg of β-estradiol 17-valerate (dissolved in 100 μL of corn oil; Sigma-Aldrich, Taufkirchen, Germany) once a week. To analyze the effect of COX-2 inhibition on the homing of EPCs in endometriotic lesions, the mice were additionally treated with the selective COX-2 inhibitor parecoxib (25 mg/kg; n = 18) or vehicle (sodium chloride; control; n = 19) by daily i.p. injections.

High-Resolution Ultrasonography and Analysis

The fixed uterine tissue samples were repetitively analyzed with a Vevo 770 high-resolution ultrasonography system (VisualSonics, Toronto, ON, Canada) by means of a real-time microvisualization 704 Scanhead (VisualSonics) with a center frequency of 40 MHz and a focal depth of 6 mm.
The mice were anesthetized with 2% isoflurane in oxygen and fixed in supine position on a heated stage, and the abdomen was chemically depilated (Nair hair removal lotion; Church & Dwight Canada Corp., Mississauga, ON, Canada). A three-dimensional reconstruction and analysis software from VisualSonics (Vevo 770 version 2.3.0) was used to analyze the ultrasound images. To measure the overall volume of developing endometriotic lesions as well as the volume of their stromal tissue and cysts by manual image segmentation, boundaries of the lesions and their cysts were outlined in parallel slices with a step size of 200 μm. Moreover, the growth of lesions and stromal tissue was calculated and the cyst-lesion ratio assessed.

At the end of the in vivo experiments, the anesthetized animals were carefully laparotomized under a stereomicroscope and the largest diameter (D1) and perpendicularly aligned diameter (D2) of the endometriotic lesions were measured by means of a digital caliper. The lesion size (S) was then calculated as follows: \( S = D1 \times D2 \times \frac{\pi}{4} \).

**Histologic Analysis and Immunohistochemistry**

Formalin-fixed specimens of endometriotic lesions and uterine horns were embedded in paraffin. Sections (3 μm thick) were cut and stained with hematoxylin and eosin according to standard procedures.

For the immunohistochemical detection of GFP⁺ EPCs incorporated into the GFP⁻ microvascular endothelium of the endometriotic lesions, a goat polyclonal anti-GFP antibody (1:50; Rockland Immunochemicals Inc., Limerick, PA) was used as primary antibody. The tissue sections were incubated with a corresponding secondary biotinylated antibody followed by avidin-peroxidase (1:50; Sigma-Aldrich). 3-Amino-9-ethylcarbazole (AEC Substrate System; Abcam, Cambridge, UK) was used as chromogen, and counterstaining was performed with Hemalaun. The fraction of GFP⁺ EPCs in the endometriotic lesions was quantitatively assessed by light microscopy (BX60; Olympus).
For the immuno-fluorescent detection of microvessels, sections were stained with a monoclonal rat anti-mouse antibody against the endothelial cell marker CD31 (1:300; Dianova, Hamburg, Germany). A goat anti-rat IgG cyanine 3 antibody (Dianova) served as secondary antibody. Cell nuclei were stained with Hoechst 33342 (1:500; Sigma-Aldrich). The microvessel density was measured using a BZ-8000 microscope (Keyence, Osaka, Japan). For this purpose, the overall number of CD31-positive microvessels within an endometriotic lesion was counted and divided by the area of stromal lesion tissue.

For this purpose, the overall number of CD31-positive microvessels within an endometriotic lesion was counted and divided by the area of stromal lesion tissue.

For the immunohistochemical detection of COX-2+ cells as well as proliferating and apoptotic cells in the stroma of the endometriotic lesions, sections were stained with a rabbit polyclonal antibody against COX-2 (1:100; Abcam), a rabbit polyclonal antibody against the proliferation marker Ki-67 (1:100; Abcam), and a rabbit polyclonal antibody against the apoptosis marker cleaved caspase (Casp)-3 (1:100; Cell Signaling, Danvers, MA). Additional sections were stained with antibodies against the lymphocyte marker CD3 (1:100; Abcam), the neutrophilic granulocyte marker myeloperoxidase (MPO) (1:100; Abcam), and the macrophage marker CD68 (1:50; Abcam). A goat anti-rabbit biotinylated antibody (ready to use; Abcam) served as secondary antibody followed by avidin-peroxidase (1:50; Sigma-Aldrich). 3-Amino-9-ethylcarbazole (AEC Substrate System; Abcam) was used as chromogen, and counterstaining was performed with Hemalaun. The fraction of COX-2+ cells and proliferating and apoptotic stromal cells and the number of CD3+ lymphocytes, MPO+ neutrophilic granulocytes, and CD68+ macrophages were assessed by counting the numbers of positive cells in four regions of interest within the endometriotic lesions.

Flow Cytometry
To analyze whether the inhibition of COX-2 also affects the number of circulating EPCs in the bloodstream, flow cytometric analyses of blood samples from parecoxib- and vehicle-treated mice were performed.14 After lysis of red blood cells and Fc blockade (CD16/CD32; BD Pharmingen, Heidelberg, Germany), the lymphocyte population was analyzed for the expression of the EPC marker stem cell antigen e1 fluorescein isothiocyanate (BD Pharmingen) and VEGF receptor (VEGFR)-2 phycoerythrin (BD Pharmingen). Isotype-identical antibodies served as controls (rat IgG2ak—fluorescein isothiocyanate—phycoerythrin; BD Pharmingen). Two-color flow cytometric analyses were performed by means of a FACScan (BD Pharmingen). Data were evaluated by the software package CellQuestPro version 3.2 (BD Pharmingen).

Experimental Protocol
In a first set of experiments, a total of 36 uterine tissue samples were transplanted in 18 GFP+Tie2+ bone marrow—reconstituted FVB/N mice exhibiting comparable morphologic features of the eutopic endometrium at days 7 (A, B, E, and F) and 28 (C, D, G, and H) after induction of endometriotic lesions in the peritoneal cavity. I–L: Immunofluorescent detection of microvessels (arrows) within the uterine horns of parecoxib- (J and L) and vehicle-treated (I and K) bone marrow—reconstituted FVB/N mice exhibiting a comparable vascularization of the eutopic endometrium at days 7 (J and L) and 28 (K and L) after induction of endometriotic lesions in the peritoneal cavity. Scale bars: 300 μm (A–D); 40 μm (E–H); 20 μm (I–L). d, days.
marrow—reconstituted animals, which received a single s.c. injection of 100 μg/kg of β-estradiol 17-valerate. The mice were randomly divided into two groups (n = 9 each), which were treated with 25 mg/kg parecoxib or vehicle (sodium chloride; control) by daily i.p. injections. After 7 days, tissue and blood samples were harvested and further processed for histologic analysis, immunohistochemical analysis, and flow cytometry.

In a second set of experiments, a total of 38 uterine tissue samples were transplanted in 19 GFP+/Tie2+ bone marrow—reconstituted animals. The mice were randomly divided into two groups receiving 100 μg/kg s.c. β-estradiol 17-valerate once a week and 25 mg/kg of parecoxib or vehicle (control; n = 10) by daily i.p. injections for 28 days. Ultrasound image analyses of the endometriotic lesions were performed directly after tissue transplantation (day 0) as well as at days 7, 14, 21, and 28. At the end of the experiments, the size of the endometriotic lesions was additionally assessed by means of a digital caliper. Tissue and blood samples were taken and further processed for histologic analysis, immunohistochemical analysis, and flow cytometry.

**Statistical Analysis**

Data were first analyzed for normal distribution and equal variance. In case of parametric data, differences between the two experimental groups were assessed by the unpaired t-test. In case of nonparametric data, differences between the two experimental groups were assessed by the Mann-Whitney rank sum test. To test for time effects within each experimental group, analysis of variance for repeated measurements was applied followed by the Dunnett post hoc test (SigmaPlot 13.0; Jandel Corporation, San Rafael, CA). All data are expressed as means ± SEM. Statistical significance was accepted for P < 0.05.

**Results**

**Growth and Cyst Formation of Endometriotic Lesions**

The growth and cyst formation of developing endometriotic lesions were repetitively analyzed by means of high-resolution ultrasonography for 28 days (Figure 2, A and B). Lesions of vehicle- and parecoxib-treated animals exhibited a comparable initial size of 1.2 mm³ at day 0 (Figure 2C). Throughout the following observation period, the growth of parecoxib-treated endometriotic lesions was markedly suppressed, resulting in a significantly lower overall lesion volume of approximately 2 mm³ at day 28 when compared with vehicle-treated controls (approximately 6 mm³) (Figure 2, A–D). More detailed analyses of the stromal and cyst-like dilated glandular parts of the lesions revealed that this was caused by an inhibition of stromal tissue proliferation during the early development of the lesions within the first 14 days after surgical induction (Figure 2, E and F). Moreover, parecoxib-treated lesions exhibited a reduced secretory activity between days 14 and 28, as indicated by significantly lower cyst volumes and cyst/lesion ratios (Figure 2, G and H).

These results were confirmed by additional histologic analyses and caliper measurements of the lesions at the end of the
**in vivo** experiments. As expected, parecoxib-treated lesions contained smaller cyst-like dilated glands when compared with vehicle-treated controls (Figure 2, I and J). In addition, their overall size was significantly reduced (Figure 2K).

**COX-2 Expression and Vascularization of Endometriotic Lesions**

Immunohistochemical analyses revealed that COX-2 expression was particularly high within the stroma of vehicle-treated control lesions at day 7 (Figure 3, A–D and I). Parecoxib treatment significantly reduced this enhanced expression of COX-2 in the initial phase of engraftment (Figure 3, B and I).

The engraftment of spread endometrial tissue at ectopic sites is associated with the formation of new microvascular networks via angiogenesis and vasculogenesis. Additional immunohistochemical analyses of the newly developing endometriotic lesions found that these two processes were also suppressed by the inhibition of COX-2. Parecoxib-treated lesions exhibited a significantly reduced microvessel density at day 7 but not at day 28 when compared with vehicle-treated controls (Figure 3, E–H and J). Previous findings indicate that there is a positive correlation between lesion vascularization and numbers of recruited EPCs. Accordingly, the microvascular endothelium of parecoxib-treated lesions also contained less incorporated GFP+ EPCs at day 7 (Figure 3, K and L). Of interest, this was still the case at day 28 (Figure 3L). The numbers of circulating stem cell antigen-1+/VEGFR-2+ EPCs were increased in the bloodstream of parecoxib-treated animals when compared with vehicle-treated controls by flow cytometry (Figure 3M).

Besides, histologic and immunohistochemical analyses of the eutopic endometrium within the uterine horns of parecoxib- and vehicle-treated animals were performed. These analyses revealed that treatment with the COX-2 inhibitor affected neither the morphologic features nor the vascularization of the tissue (Figure 4).

**Cell Proliferation and Apoptotic Cell Death in Endometriotic Lesions**

A sufficient vascularization is the major prerequisite for the proliferation and survival of endometriotic lesions. Accordingly, a significantly lower number of proliferating Ki-67+ cells were detected in the endometrial stroma of parecoxib-treated lesions at day 7 but not at day 28 when compared with vehicle-treated controls (Figure 5, A–D and I). In addition, parecoxib-treated lesions contained more apoptotic Casp-3+ cells at days 7 and 28 (Figure 5, E–H and J).

**Immune Cell Infiltration into Endometriotic Lesions**

Because the COX-2 signaling pathway is a major regulator of inflammatory processes, immune cell infiltration into the endometriotic lesions was analyzed. Immunohistochemical staining of different immune cell subpopulations revealed that the lesions were primarily infiltrated by CD68+ macrophages and MPO+ neutrophilic granulocytes, whereas only a few infiltrating CD3+ lymphocytes could be detected within the endometrial stroma (Figure 6, A–L). Treatment with parecoxib suppressed this immune cell infiltration, as indicated by significantly reduced numbers of CD68+ macrophages and MPO+ neutrophilic granulocytes when compared with vehicle-treated controls (Figure 6, M–O).

**Discussion**

An increasing number of studies suggest the inhibition of COX-2 signaling for the treatment of angiogenesis-related diseases. This therapeutic approach has also been proven to be successful in preclinical endometriosis models. Machado et al reported that parecoxib treatment down-regulates the expression of VEGF and its receptor Flk-1, which results in a reduced vascularization and growth of endometriotic lesions in rats. Potent anti-VEGF effects on endometriosis have also been observed with the COX-2 inhibitor NS398 in vitro and in vivo. Moreover, Jana et al recently reported that suppression of COX-2/PGE2/phospho-AKT signaling attenuates matrix metalloproteinase-2–mediated angiogenesis in murine endometriotic lesions. In the present study, we provide evidence that vasculogenesis is another important COX-2–regulated process that contributes to blood vessel formation in endometriosis. In fact, treatment with parecoxib inhibits the incorporation of circulating EPCs in the microvasculature of endometriotic lesions and, thus, affects their vascularization in the initial phase of engraftment.

For the in vivo experiments, a previously established murine GFP+/GFP− crossover design model was used. This model involves the transplantation of GFP+ bone marrow from transgenic FVB/N-TgN (Tie2/GFP) 287 Sato mice into irradiated FVB/N wild-type animals. Importantly, we recently found that this procedure leads to low estrogen levels in the recipients, which are similar to those measured in ovariectomized mice. Accordingly, we substituted the animals with β-estradiol 17-valerate once a week to analyze the effect of COX-2 inhibition on the homing of EPCs in endometriotic lesions under physiologic estrogen levels. For this purpose, the lesions were surgically induced in the peritoneal cavity by fixation of uterine tissue samples to the abdominal wall. This approach allowed the repetitive analysis of developing endometriotic lesions by means of 40-MHz high-resolution ultrasonography. In contrast to conventional approaches for the assessment of lesion sizes, such as caliper and weight measurements, this technology bears the major advantage that stromal and cyst-like dilated glandular parts of the lesions can be easily identified and separately analyzed. Hence, it is possible to clearly differentiate between stromal tissue growth and enhanced
glandular secretory activity, which both can contribute to an increase of lesion size over time.

The ultrasound analyses revealed that stromal tissue growth was suppressed in parecoxib-treated lesions during the first 14 days after surgical induction. Additional immunohistochemical analyses found that this was associated with a significantly reduced expression of COX-2 at day 7 when compared with vehicle-treated controls. This observation is in line with previous studies reporting that parecoxib not only inhibits the activity of COX-2 but also suppresses the expression of the enzyme.38,39

In the initial phase of engraftment, ectopic endometrial tissue is particularly dependent on the rapid establishment of a functional microvasculature to guarantee a sufficient oxygen and nutrient supply,40,41 which is a major prerequisite for cell survival and proliferative activity. However, the early vascularization of the lesions was impaired in parecoxib-treated animals, as indicated by a significantly lower microvessel density at day 7 when compared with vehicle-treated controls. This finding may explain the lower number of Ki-67{sup}þ{}/papilloma cells and higher number of Casp-3{sup}þ{}/apoptotic cells within the lesions at this early time point. On the other hand, inhibition of COX-2 directly affects proliferation and viability of malignant and benign cells and tissues.42–44 Accordingly, parecoxib-treated lesions still exhibited increased numbers of apoptotic cells at day 28. It may be assumed that the engraftment of the lesions, which is associated with a high vascularization activity and cell turnover, was finally completed in the two experimental groups at this late time point. Hence, although a delayed vascularization was detected under COX-2 treatment, the lesions of the two groups no longer differed in terms of microvessel density and numbers of proliferating Ki-67{sup}þ{}/papilloma cells. Nonetheless, even at day 28, a significantly reduced number of EPCs were detected in the microvasculature of parecoxib-treated lesions when compared with vehicle-treated controls. This finding suggests that the continuous self-renewal process of the microvascular endothelium via the incorporation of circulating EPCs was still impaired by parecoxib treatment in this late phase of lesion development, which is particularly characterized by microvascular network maturation and remodeling.14

Of interest, blockade of COX-2/PGE{sub}2 signaling was found to reduce the secretory activity of endometrial glands, as indicated by a markedly decreased cyst volume and cyst/lesion ratio of parecoxib-treated lesions between days 21

Figure 6 A–L: Immunohistochemical detection of CD68{sup}þ{}/macrophages (A–D, arrows), myeloperoxidase (MPO){sup}þ{}/neutrophilic granulocytes (E–H, arrows), and CD3{sup}þ{}/lymphocytes (I–L, arrows) in the stroma of endometriotic lesions at days 7 (A, B, E, F, I, and J) and 28 (C, D, G, H, K, and L) after transplantation of uterine tissue samples into the peritoneal cavity of bone marrow–reconstituted FVB/N mice, which received β-estradiol 17-valerate once a week and were additionally treated with parecoxib (B, D, F, H, J, and L) or vehicle (A, C, E, G, I, and K) by daily i.p. injections. M–O: CD68{sup}þ{}/macrophages (M), MPO{sup}þ{}/neutrophilic granulocytes (N), and CD3{sup}þ{}/lymphocytes (O) in the stroma of endometriotic lesions of bone marrow–reconstituted FVB/N mice, which received β-estradiol 17-valerate once a week and were additionally treated with parecoxib (black bars) or vehicle (white bars) by daily i.p. injections throughout an observation period of 7 and 28 days. Data are expressed as means ± SEM. n = 9 parecoxib-treated mice (M–O); n = 9 to 10 vehicle-treated mice (M–O). *P < 0.05 versus vehicle. Scale bars = 20 μm (A–L). d, days.
and 28. In line with this result, COX-2 seems to be crucially involved in the regulation of water-transporting aquaporins.\textsuperscript{45} In addition, PGE\textsubscript{2} has been reported to stimulate other secretory processes.\textsuperscript{46–48} In line with this result, COX-2 seems to be crucially involved in the regulation of water-transporting aquaporins.\textsuperscript{45} In addition, PGE\textsubscript{2} has been reported to stimulate other secretory processes.\textsuperscript{46–48} The observed inhibitory action of parecoxib on vasculogenesis in endometriotic lesions may be attributable to different effects on EPCs. Colleselli et al\textsuperscript{46} reported that inhibition of COX-2 causes a significant reduction of EPC proliferation by inducing apoptosis and cell cycle arrest. This direct effect on the viability of EPCs may also affect their incorporation into newly developing microvessels. In addition, COX-2 inhibition may interfere with trafficking mechanisms that mediate the mobilization of EPCs from the bone marrow into the bloodstream and their subsequent recruitment in endometriotic lesions. Decreased stromal cell–derived factor (SDF)-1 levels in the bone marrow increase the mobilization of EPCs and other stem cells into the bloodstream.\textsuperscript{49,50} On the other hand, suppression of the SDF-1/chemokine receptor type 4 axis also inhibits the recruitment of EPCs in endometriotic lesions.\textsuperscript{11,13} Considering the fact that COX-2 inhibition down-regulates SDF-1 expression,\textsuperscript{51} these findings fit well with our observation that the number of circulating EPCs was significantly higher, whereas the number of EPCs incorporated into the microvascular endothelium of endometriotic lesions was significantly lower in parecoxib-treated mice when compared with vehicle-treated controls.

Finally, it is well known that endometriotic lesions generate a proinflammatory environment in the peritoneal cavity, which may also be a major cause for endometriosis-associated pain.\textsuperscript{72} Accordingly, targeting COX-2 is a promising approach to suppress different inflammatory mechanisms, such as the production of proinflammatory cytokines and the activation of immune cells.\textsuperscript{53–54} Therefore, we additionally analyzed in this study the effect of parecoxib on immune cell infiltration in endometriotic lesions. Of interest, the endometriotic lesions were mainly infiltrated by macrophages and neutrophilic granulocytes, whereas only a few lymphocytes could be detected in the endometrial stromal tissue. The latter observation contradicts the results of previous studies that reported that lymphocytes are a major immune cell subpopulation in murine and human endometriotic lesions.\textsuperscript{55,56} However, in the present experimental setting, the analyzed mice underwent irradiation and bone marrow transplantation. Hence, these interventions may change the ratios of individual immune cell subsets or their response to the ectopic endometrial tissue in the peritoneal cavity.

Taken together, the present study found that inhibition of COX-2 suppresses the recruitment of EPCs in the microvasculature of endometriotic lesions. Therefore, COX-2 inhibitors may be suitable to suppress vasculogenesis in endometriosis. Besides the well-known antiangiogenic, antiproliferative, anti-inflammatory, analgesic, and pro-apoptotic activity of COX-2 inhibitors, this novel mechanism may further contribute to their beneficial action profile in the treatment of endometriosis. Such a treatment may be particularly effective to prevent the formation of early engrafting red lesions, which are characterized by a high vascularization rate and many immature microvessels.\textsuperscript{4,47} In contrast, older black and white lesions that exhibit fewer microvessels and more fibrous tissue may be more resistant. Moreover, therapeutic approaches that target the formation of new blood vessels in endometriotic lesions may also affect physiologic angiogenesis in the reproductive organs. Our observation that the vascularization of the eutopic endometrium in the uterus was comparable in parecoxib- and vehicle-treated animals indicates that this was not the case in the present study. However, additional studies analyzing in more detail the effects of COX-2 inhibitors on the female reproductive system are needed to clarify in which phases of endometriosis therapy these drugs may be useful without inducing severe adverse effects.
